Moss and Adams' Heart Disease in Infants, Children, and Adolescents

Including the Fetus and Young Adult

EIGHTH EDITION VOLUME I

EDITORS

Hugh D. Allen, MD, FACC, FAAP, FAHA

Professor of Pediatrics (Cardiology)
Baylor College of Medicine
Staff Cardiologist
Texas Children's Hospital
Houston, Texas

David J. Driscoll, MD

Professor of Pediatrics
Division of Pediatric Cardiology
Department of Pediatric and Adolescent
Medicine
Mayo Clinic College of Medicine
Mayo Clinic Foundation
Rochester, Minnesota

Robert E. Shaddy, MD

Professor of Pediatrics
Department of Pediatrics
University of Pennsylvania Perelman
School of Medicine
Chief, Division of Pediatric Cardiology
Vice Chair, Department of Pediatrics
The Children's Hospital of Pennsylvania
Philadelphia, Pennsylvania

Timothy F. Feltes, MD

Andy Paxon Chair in Cardiology
Co-Director of the Heart Center
Chief, Pediatric Cardiology
Professor of Pediatrics
The Ohio State University
Nationwide Children's Hospital
Columbus, Ohio

Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: at LWW.com. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6 pm, EST.

Dedication

*To my grandchildren, Christopher, Stella,
and Adam, and to my families at home as
well as at work.*

—HDA

*To my grandchildren, Brendan and
Emmaleine.*

—DJD

*To family and friends for their patience and
support.*

—RES

*Jethro got it right; life's a long song starting
with you, Mr. Johnson. But was the deal
worth it? It may be a buckdancer's choice
to travel with traffic or to take the lonely
Ventura Highway, but we always seem to
end up in Winslow Arizona. To Taj, Ste-
vie Rae, John Lee, Lightnin', Eric, and the
King himself, thanks for the tunes boys.
Pete, glad the Detours name didn't stick but
then the "lead balloon" did! And to Club
27's Jim, Jimi, and Janis, your poetry lives
on. I'm bad...I'm Nationwide!*

—TFF

CONTENTS

Contributors ix
 Preface xvii
 Acknowledgments xviii
 Tribute to Moss, Adams, & Emmanouilides xix
 The Development of Pediatric Cardiology: Historical
 Milestones <http://solution.lww.com>

VOLUME I

SECTION I:

Structure and Function of the Cardiovascular System 1

- 1 Cardiac Anatomy and Examination of Cardiac Specimens 1
 William D. Edwards and Joseph J. Maleszewski
- 2 Classification and Terminology of Cardiovascular Anomalies 32
 William D. Edwards and Joseph J. Maleszewski
- 3 Development of Myocardial Structure and Function 52
 Pamela A. Lucchesi, Kirk R. Hutchinson, Luciana Martins, and Loren E. Wold
- 4 Circulation Physiology 69
 David F. Teitel, Steven C. Cassidy, and Jeffrey R. Fineman

SECTION II:

Diagnostic and Therapeutic Methods 82

- 5 History and Physical Examination 82
 Steven C. Cassidy, Hugh D. Allen, and John R. Phillips
- 6 Exercise Screening and Sports Participation. 93
 Julie A. Brothers, Paul Stephens, Jr., and Stephen M. Paridon
- 7 Exercise Testing 118
 Paolo T. Pianosi and David J. Driscoll
- 8 Echocardiography: Basic Principles and Imaging 134
 Thomas R. Kimball and Erik C. Michelfelder
- 9 Echocardiographic Assessment of Cardiac Dimensions, Cardiac Function, and Valve Function 172
 Luc L. Mertens and Mark K. Friedberg
- 10 Magnetic Resonance Imaging. 207
 Tal Geva and Andrew J. Powell

- 11 Cardiac Computed Tomography in Children with Congenital Heart Disease 247
 Frederick R. Long and Joachim G. Eichhorn
- 12 Cardiac Catheterization and Angiography 258
 Nathaniel W. Taggart and Allison K. Cabalka
- 13 Therapeutic Cardiac Catheterization . . 288
 Ralf J. Holzer and John P. Cheatham

SECTION III:

Electrophysiology 348

- 14 Development and Functional Maturation of the Cardiac Conduction System 348
 Aleksander Sizarov, Antoon F.M. Moorman, and Arthur S. Pickoff
- 15 The Normal Electrocardiogram 372
 George F. Van Hare and Anne M. Dubin
- 16 Cardiac Channelopathies, Syncope, and Sudden Death 389
 Michael J. Ackerman
- 17 Electrophysiology Studies and Electrophysiologic Therapeutic Catheterization. 401
 J. Philip Saul and John D. Kugler
- 18 Disorders of Cardiac Rhythm and Conduction 441
 Bryan C. Cannon and Christopher S. Snyder

SECTION IV:

Pediatric Cardiac Intensive Care 473

- 19 Physiology of the Preterm and Term Infant. 473
 Timothy M. Hoffman and Stephen E. Welty
- 20 Pediatric Cardiovascular Intensive Care 483
 Dean B. Andropoulos and Anthony C. Chang
- 21 Cardiac Mechanical Support Therapies 530
 Elizabeth D. Blume, Ravi R. Thiagarajan, and Peter C. Laussen

- 22** Cardiopulmonary and Right-Left Heart Interactions 546
Andrew N. Redington
- 23** Cardiac Trauma 552
Gary A. Smith and Timothy F. Feltes

SECTION V:**From the Gene to the Neonate 560**

- 24** Molecular Determinants of Cardiac Development and Disease. 560
Deepak Srivastava and H. Scott Baldwin
- 25** Epidemiology and Prevention of Congenital Heart Defects. 577
Lorenzo D. Botto
- 26** Genetic Aspects of Congenital Heart Defects. 617
Elizabeth Goldmuntz, Melissa L. Crenshaw, and Angela E. Lin
- 27** Fetal Echocardiography and Fetal Cardiology 644
Charles S. Kleinman, Julie S. Glickstein, Ganga Krishnamurthy, and Jodie K. Votava-Smith

SECTION VI:**Congenital Cardiovascular Malformations 672****PART A: Septal Defects**

- 28** Atrial Septal Defects. 672
Ritu Sachdeva
- 29** Atrioventricular Septal Defects. 691
Frank Cetta, Luann L. Minich, Joseph J. Maleszewski, Joseph A. Dearani, and Harold MacDonald Burkhardt
- 30** Ventricular Septal Defects 713
Agustin E. Rubio and Mark B. Lewin

PART B: Arterial Abnormalities

- 31** Patent Ductus Arteriosus and Aortopulmonary Window 722
Phillip Moore and Michael M. Brook
- 32** Congenital Anomalies of the Coronary Vessels and the Aortic Root 746
D. Scott Lim and G. Paul Matherne
- 33** Aortic Arch and Vascular Anomalies 758
Paul M. Weinberg, Shobha Natarajan, and Lindsay S. Rogers
- 34** Abnormalities of the Aortic Root. 799
Matina Prapa, John Pepper, and Michael A. Gatzoulis

VOLUME II**PART C: Venous Abnormalities**

- 35** Anomalies of the Pulmonary Veins. . . 809
David W. Brown and Tal Geva
- 36** Abnormal Systemic Venous Connections 840
Tal Geva
- 37** Vascular Tumors and Anomalies 864
Ahmad I. Alomari
- 38** Tricuspid Atresia, Stenosis, Regurgitation, and Uhl's Anomaly . . . 877
Michael L. Epstein
- 39** Ebstein's Anomaly, Congenital Tricuspid Valve Regurgitation, and Dysplasia. 889
Sameh M. Said and Joseph A. Dearani
- 40** Pulmonary Stenosis 913
Lourdes R. Prieto and Larry A. Latson
- 41** Pulmonary Atresia and Intact Ventricular Septum 939
David G. Nykanen
- 42** Pulmonary Atresia and Ventricular Septal Defect 959
Patrick W. O'Leary, William D. Edwards, Paul R. Julsrud, and Harold MacDonald Burkhardt
- 43** Tetralogy of Fallot with Pulmonary Stenosis and Tetralogy of Fallot with Absent Pulmonary Valve 969
S. Lucy Roche, Steven C. Greenway, and Andrew N. Redington

PART D: Left Ventricular Inflow and Outflow Abnormalities

- 44** Truncus Arteriosus. 990
Allison K. Cabalka, William D. Edwards, and Joseph A. Dearani
- 45** Anatomical and Functional Mitral Valve Abnormalities in the Pediatric Population 1003
Andrew S. Mackie and Jeffrey F. Smallhorn
- 46** Aortic Stenosis 1023
Douglas J. Schneider and John W. Moore
- 47** Coarctation of the Aorta 1044
Robert H. Beekman, III
- 48** Hypoplastic Left Heart Syndrome . . 1061
James S. Tweddell, George M. Hoffman, Nancy S. Ghanayem, Michele A. Frommelt, Kathleen A. Mussatto, and Stuart Berger

PART E: Abnormalities of the Origin of the Great Arteries

- 49** Transposition of the Great Arteries . . . 1097
Gil Wernovsky

- 50** Congenitally Corrected Transposition of the Great Arteries (Atrioventricular and Ventriculoarterial Discordance) . . . 1147
Joseph Atallah, Jennifer M. Rutledge, and John D. Dyck

PART F: Complex Cardiac Abnormalities

- 51** Double Outlet Right Ventricle . . . 1161
Gail E. Wright, Katsuhide Maeda, Norman H. Silverman, Frank L. Hanley, and Stephen J. Roth

- 52** Univentricular Atrioventricular Connection. 1175
Michael G. Earing, Donald J. Hagler, and William D. Edwards

- 53** Cardiac Malpositions and Abnormalities of Atrial and Visceral Situs. 1195
Patrick W. O'Leary and Donald J. Hagler

SECTION VII:

Diseases of the Endocardium, Myocardium, and Pericardium 1217

- 54** Hypertrophic Cardiomyopathy . . . 1217
Barry J. Maron

- 55** Dilated Cardiomyopathy 1235
Timothy M. Olson and David P. Chan

- 56** Myocarditis 1247
Jeffrey A. Towbin, Angela Lorts, and John Lynn Jefferies

- 57** Restrictive Cardiomyopathy. 1267
Susan W. Denfield

- 58** The Heart in Muscular Dystrophies. . . 1277
Hugh D. Allen, Jerry R. Mendell, Kevin M. Flanigan, and Timothy M. Hoffman

- 59** Kawasaki Disease (Mucocutaneous Lymph Node Syndrome) 1287
Sarah D. De Ferranti and Jane W. Newburger

- 60** Rheumatic Fever and Rheumatic Heart Disease. 1303
Lloyd Y. Tani

- 61** Inflammatory Noninfectious Cardiovascular Diseases. 1331
Charles H. Spencer, Anjali Patwardhan, and Sharon L. Roble

- 62** Pericardial Diseases 1350
Jonathan N. Johnson and Frank Cetta

- 63** Infective Endocarditis and Prevention 1363
Michael Gewitz and Kathryn A. Taubert

- 64** Myocardial Ischemia 1377
Ali N. Zaidi and Curt J. Daniels

- 65** Pediatric Heart Transplantation. . . . 1384
Robert E. Shaddy and Francesco Parisi

SECTION VIII:

Pulmonary Vascular Disease 1401

- 66** Pathophysiology of Pulmonary Hypertension 1401
Marlene Rabinovitch

- 67** Clinical Management of Pediatric Pulmonary Arterial Hypertension. . . 1433
D. Dunbar Ivy

SECTION IX:

The Young Adult with Congenital Heart Disease 1463

- 68** The Adolescent and Adult with Congenital Heart Disease. . . . 1463
Ali N. Zaidi and Curt J. Daniels

- 69** Pregnancy in Young Women with Congenital Heart Disease. . . . 1494
Candice K. Silversides, Jack M. Colman, and Samuel C. Siu

SECTION X:

Other Special Problems and Issues 1509

- 70** Chest Pain in Children and Adolescents 1509
Jonathan N. Johnson and David J. Driscoll

- 71** Coronary Risk Factors in Children. . 1514
Stephen R. Daniels

- 72** Cardiac Tumors 1549
Gerald R. Marx and Adrian M. Moran

- 73** Chronic Heart Failure in Children . . 1565
Robert E. Shaddy and Lloyd Y. Tani

- 74** Neurodevelopmental Outcomes after Heart Surgery in Children . . . 1579
Caren S. Goldberg and Jane W. Newburger

- 75** Hematologic Aspects of Pediatric and Adolescent Heart Disease: Bleeding, Clotting, and Blood Component Abnormalities 1589
Therese M. Giglia and Char Witmer

76 Evaluation of Quality of Life in Children
and Adolescents with Congenital and
Acquired Heart Disease1608

Bradley S. Marino

77 Safety and Quality in the Heart
Center1622

Anthony Y. Lee, Thomas Taghon, Richard Eugene McClead, Jr.,
Terrance Davis, and Richard J. Brilli

78 Design, Execution, and Appraisal
of Clinical Trials1636

Brian W. McCrindle

79 Pharmacology1661

Michael Artman and Gregory L. Kearns

Index I-1

CONTRIBUTORS

Michael J. Ackerman, MD, PhD, FACC

Windland Smith Rice Cardiovascular
Genomics Research Professor
Professor of Medicine, Pediatrics, and
Pharmacology
Director, Long QT Syndrome/Genetic
Heart Rhythm Clinic
Director, Windland Smith Rice Sudden
Death Genomics Laboratory
Medicine, Pediatrics, and Molecular
Pharmacology and Experimental
Therapeutics
Mayo Clinic
Rochester, Minnesota

Hugh D. Allen, MD, FACC, FAAP, FAHA

Professor of Pediatrics (Cardiology)
Baylor College of Medicine
Staff Cardiologist
Texas Children's Hospital
Houston, Texas

Ahmad I. Alomari, MD, MSc

Assistant Professor
Division of Vascular and Interventional
Radiology
Children's Hospital Boston
Harvard Medical School
Boston, Massachusetts

Dean B. Andropoulos, MD

Professor of Anesthesiology
Director, Pediatric Cardiovascular
Anesthesia
Texas Children's Hospital
Houston, Texas

Michael Artman, MD

Chair
Department of Pediatrics
School of Medicine
University of Missouri–Kansas City
Joyce C. Hall Distinguished Professor
and Chair
Department of Pediatrics
Children's Mercy Hospitals and Clinics
Kansas City, Missouri

Joseph Atallah, MD CM, MSc(Epi), FRCP

Assistant Professor
Departments of Pediatrics and Public
Health Sciences
University of Alberta
Attending Staff
Departments of Pediatrics and Medicine
Stollery Children's Hospital and Univer-
sity of Alberta Hospital
Edmonton, Alberta, Canada

H. Scott Baldwin, MD

Professor of Pediatrics and Cell and
Developmental Biology
Chief, Division of Pediatric
Cardiology
Co-Director of the Pediatric Heart
Institute
Vanderbilt Children's Hospital
Nashville, Tennessee

Robert H. Beekman, III, MD

Professor
Department of Pediatric
Cardiology
University of Cincinnati College of
Medicine
Professor
Heart Institute
Cincinnati Children's Hospital Medical
Center
Cincinnati, Ohio

Stuart Berger, MD

Professor of Pediatrics
The Medical College of Wisconsin
Medical Director of the Herma Heart
Center
Children's Hospital of Wisconsin
Milwaukee, Wisconsin

Elizabeth D. Blume, MD

Associate Professor
Department of Pediatrics
Harvard Medical School
Medical Director, Heart Failure and
Transplant Program
Department of Cardiology
Children's Hospital, Boston
Boston, Massachusetts

Lorenzo D. Botto, MD

Professor of Pediatrics
Department of Pediatrics
University of Utah
Attending Physician
Division of Medical Genetics
Primary Children's Medical
Center
Salt Lake City, Utah

Richard J. Brilli, MD

Professor
Department of Pediatrics
The Ohio State University College of
Medicine
Chief Medical Officer
Hospital Administration
Nationwide Children's Hospital
Columbus, Ohio

Michael M. Brook, MD

Professor of Clinical Pediatrics
Director, Pediatric and Congenital
Echocardiography
University of California–San Francisco
Benioff Children's Hospital
San Francisco, California

Julie A. Brothers, MD

Assistant Professor
Department of Pediatrics
Perelman School of Medicine at the
University of Pennsylvania
Medical Director, Lipid Heart Clinic
Division of Cardiology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

David W. Brown, MD

Assistant Professor
Department of Pediatrics
Harvard Medical School
Associate
Department of Cardiology
Children's Hospital Boston
Boston, Massachusetts

Harold MacDonald Burkhardt, MD

Associate Professor of Surgery/
Cardiovascular Surgeon
Department of Cardiovascular Surgery
Mayo Clinic
Rochester, Minnesota

Allison K. Cabalka, MD, FACC, FASE, FSCAI

Associate Professor of Pediatrics
Division of Pediatric Cardiology
Mayo Clinic
Rochester, Minnesota

Bryan C. Cannon, MD

Associate Professor
Department of Pediatrics
Director
Pediatric Arrhythmia and
Pacing Service
Mayo Clinic
Rochester, Minnesota

Steven C. Cassidy, MD

Associate Professor
Department of Pediatrics
Ohio State University College of
Medicine
Director, Inpatient Services
Heart Center
Nationwide Children's Hospital
Columbus, Ohio

Frank Cetta, MD

Professor of Medicine and Pediatrics
Divisions of Pediatric Cardiology and
Cardiovascular Diseases
Chief
Division of Pediatric Cardiology
Mayo Clinic
Rochester, Minnesota

David P. Chan, MD

Professor of Clinical Pediatrics
Department of Pediatrics
University of Illinois College of
Medicine Peoria
Division Head Pediatric Cardiology
Department of Pediatrics
Children's Hospital of Illinois
Peoria, Illinois

Anthony C. Chang, MD, MBA, MPH

Medical Director
Heart Institute at Children's Hospital
of Orange County
Orange California
Associate Professor of Pediatrics
University of California, Irvine
Irvine, California

John P. Cheatham, MD, FAAP, FACC, FSCAI

Professor
Department of Pediatrics and Internal
Medicine
The Ohio State University
Co-Director, The Heart Center
Director of Cardiac Catheterization
and Interventional Therapy
Heart Center
Nationwide Children's Hospital
Columbus, Ohio

Jack M. Colman, MD, FRCPC

Professor of Medicine and Obstetrics &
Gynecology Division of Cardiology
University of Toronto
Mount Sinai Hospital and Peter Munk
Cardiac Centre/University Health
Network
Toronto Congenital Cardiac Centre for
Adults
Toronto, Ontario, Canada

Melissa L. Crenshaw, MD

Medical Director
Clinical Genetics
All Children's Hospital, a member of
Johns Hopkins Medicine
St. Petersburg, Florida

Curt J. Daniels, MD

Associate Professor
Internal Medicine and Pediatrics
Director, Columbus Ohio Adult
Congenital Heart Disease and
Pulmonary Hypertension Program
National Children's Hospital
The Ohio State University
Columbus, Ohio

Stephen R. Daniels, MD, PhD

Professor and Chairman
Department of Pediatrics
University of Colorado School of
Medicine
Pediatrician-in-Chief
L. Joseph Butterfield Chair of Pediatrics
Children's Hospital Colorado
Aurora, Colorado

Terrance Davis, MD

Professor Emeritus of Clinical Surgery
Department of Surgery
The Ohio State University
Associate CMO, Co-Medical Director
for Patient Safety
Department of Administration
Nationwide Children's Hospital
Columbus, Ohio

Sarah D. De Ferranti, MD, MPH

Assistant Professor of Pediatrics
Harvard Medical School
Director, Preventive Cardiology Clinic
Boston Children's Hospital
Boston, Massachusetts

Joseph A. Dearani, MD

Professor of Surgery
Chair, Cardiovascular Surgery
Division of Cardiovascular Surgery
Mayo Clinic
Rochester, Minnesota

Susan W. Denfield, MD

Associate Professor
Department of Pediatrics
Division of Pediatric Cardiology
Baylor College of Medicine
Texas Children's Hospital
Houston, Texas

David J. Driscoll, MD

Professor of Pediatrics
Division of Pediatric Cardiology
Department of Pediatrics
Mayo Clinic, Mayo Clinic College of
Medicine, and Mayo Foundation
Rochester, Minnesota

Anne M. Dubin, MD

Associate Professor
Department of Pediatrics
Stanford University
Director of Pediatric Arrhythmia Service
Department of Pediatric Cardiology
Lucile Packard Children's Hospital
Palo Alto, California

D. Dunbar Ivy, MD

Professor
Department of Pediatrics
University of Colorado
Chief and Selby's Chair
Director, Pediatric Pulmonary
Hypertension Program
Children's Hospital, Colorado
Aurora, Colorado

John D. Dyck, MD, FRCP(C)

Professor
Department of Pediatrics
University of Alberta
Director of Pediatric
Cardiology
Department of Pediatrics (Pediatric
Cardiology)
Stollery Children's hospital
Edmonton, Alberta, Canada

Michael G. Earing, MD

Associate Professor
Departments of Internal Medicine and
Pediatrics
Divisions of Adult Cardiovascular
Medicine and Pediatric
Cardiology
Medical College of Wisconsin
Director of the Adult Congenital Heart
Disease Program
Children's Hospital of Wisconsin
Milwaukee, Wisconsin

William D. Edwards, MD

Professor of Pathology
Laboratory Medicine and Pathology
Mayo Clinic
Rochester, Minnesota

Joachim G. Eichhorn, MD

Privatdozent
Department of Pediatrics
Ruperto Carola University
Deputy Chief
Department of Pediatric Cardiology/
Congenital Heart Disease
University Children's Hospital
Heidelberg, Germany

Michael L. Epstein, MD

Affiliate Professor
Department of Pediatrics
University of South Florida College of
Medicine
Tampa, Florida
Senior Vice President for Medical
Affairs
All Children's Hospital
St. Petersburg, Florida

Timothy F. Feltes, MD

Professor of Pediatrics
Department of Pediatrics
The Ohio State University
Chief of Cardiology, Co-Director of the
Heart Center
Nationwide Children's Hospital
Columbus, Ohio

Jeffrey R. Fineman, MD

Professor of Pediatrics
Division Chief, Critical
Care Medicine
University of California,
San Francisco
San Francisco, California

Kevin M. Flanigan, MD

Professor of Pediatrics and Neurology
Department of Pediatrics
Ohio State University
Professor
Center for Gene Therapy
Nationwide Children's Hospital
Columbus, Ohio

Mark K. Friedberg, MD

Associate Professor
Department of Pediatrics
University of Toronto
Cardiologist
Department of Cardiology
The Hospital for Sick Children
Toronto, Ontario, Canada

Michele A. Frommelt, MD

Associate Professor
Department of Pediatrics
Medical College of Wisconsin
Staff Physician
Department of Pediatric Cardiology
Children's Hospital of Wisconsin
Milwaukee, Wisconsin

Michael A. Gatzoulis, MD, PhD, FACC, FESC

Professor of Cardiology
Congenital Heart Disease
Consultant Cardiologist
Royal Brompton Hospital
National Heart & Lung Institute
Imperial College
London, England, United Kingdom

Tal Geva, MD

Professor
Department of Pediatrics
Harvard Medical School
Chief, Division of Noninvasive
Imaging
Department of Cardiology
Children's Hospital Boston
Boston, Massachusetts

Michael Gewitz, MD

Physician-in-Chief
Chief, Pediatric Cardiology
Maria Fareri Children's Hospital at
Westchester Medical Center
Professor and Vice Chairman
Department of Pediatrics
New York Medical College
Valhalla, New York

Nancy S. Ghanayem, MD

Associate Professor
Department of Pediatrics, Division of
Critical Care
Medical College of Wisconsin
Clinical Director, Cardiac
Critical Care
Children's Hospital of Wisconsin
Milwaukee, Wisconsin

Therese M. Giglia, MD, FACC, FAAP, SCCM

Attending Cardiologist
Cardiac Center
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Julie S. Glickstein, MD, FAAP, FAAC

Clinical Professor of Pediatrics
Department of Pediatrics
Columbia University College of
Physicians and Surgeons
Attending Physician
Department of Pediatrics,
Division of Pediatric Cardiology
Children's Hospital of New York
Presbyterian
New York, New York

Caren S. Goldberg, MD, MS

Associate Professor
Department of Pediatrics
University of Michigan Medical Center
Pediatric Cardiologist
Department of Pediatrics, Division of
Pediatric Cardiology
C.S. Mott Children's Hospital
Ann Arbor, Michigan

Elizabeth Goldmuntz, MD

Associate Professor of Pediatrics
Department of Pediatrics
University of Pennsylvania Perelman
School of Medicine
Associate Physician
Division of Cardiology, Department of
Pediatrics
The Children's Hospital of
Philadelphia
Philadelphia, Pennsylvania

Steven C. Greenway, MSc, MD, FRCPC

Clinical Fellow
Labatt Family Heart Centre
The Hospital for Sick Children
Toronto, Ontario, Canada

Donald J. Hagler, MD

Professor of Pediatrics and Medicine
Department of Pediatrics and Medicine
Pediatric Cardiology and Cardiovascu-
lar Diseases
Pediatric Cardiac Catheterization
Laboratory
Mayo Clinic College of Medicine
Rochester, Minnesota

Frank L. Hanley, MD

Co-Director and Professor of
Cardiothoracic Surgery
Children's Heart Center
Lucile Packard Children's Hospital at
Stanford
Stanford, California

George M. Hoffman, MD

Medical Director
Division of Anesthesiology
Children's Hospital of Wisconsin
Professor, Anesthesiology and Critical
Care
Medical Director and Chief, Pediatric
Anesthesiology
Associate Director, Pediatric Intensive
Care Unit
Medical College of Wisconsin
Milwaukee, Wisconsin

Timothy M. Hoffman, MD

Associate Professor
Department of Pediatrics
The Ohio State University College of
Medicine
Medical Director, Heart Transplant
and Heart Failure Program
The Heart Center
Nationwide Children's Hospital
Columbus, Ohio

Kirk R. Hutchinson, PhD, MS

Department of Physiology
The University of Arizona
Tucson, Arizona

Ralf J. Holzer, MD

Associate Professor of Pediatrics
The Ohio State University Medical
Center
Assistant Director
The Heart Center Cardiac
Catheterization and Interventional
Therapy
Nationwide Children's Hospital
Columbus, Ohio

John Lynn Jefferies, MD, MPH, FAAP, FACC

Associate Professor, Pediatric
Cardiology and Adult Cardiovascu-
lar Diseases
Director, Advanced Heart Failure,
Cardiomyopathy, and Ventricular
Assist Device Programs
Co-Director, Cardiovascular Genetics
Associate Director, Heart Institute
Research Core
The Heart Institute
Cincinnati Children's Hospital Medical
Center
Cincinnati, Ohio

Jonathan N. Johnson, MD

Assistant Professor
Department of Pediatrics
Mayo Clinic College of Medicine
Senior Associate Consultant
Department of Pediatrics, Division of
Pediatric Cardiology
Mayo Clinic
Rochester, Minnesota

Paul R. Julsrud, MD

Professor of Radiology
College of Medicine
Consultant
Department of Radiology
Mayo Clinic
Rochester, Minnesota

Gregory L. Kearns, PharmD, PhD

Professor
Department of Pediatrics and
Pharmacology
University of Missouri–Kansas City
Chairman
Medical Research
The Children's Mercy Hospital
Kansas City, Missouri

Thomas R. Kimball, MD

Professor
Department of Pediatrics
University of Cincinnati College of
Medicine
Medical Director
Heart Institute
Cincinnati Children's Hospital Medical
Center
Cincinnati, Ohio

Ganga Krishnamurthy, MBBS

Assistant Professor
Department of Pediatrics
Columbia University
Director, Neonatal Cardiac Care
Department of Pediatrics
Morgan Stanley Children's Hospital of
New York
New York, New York

John D. Kugler, MD

DB & Paula Varner Professor of
Pediatrics
Professor of Internal Medicine
Department of Pediatrics
University of Nebraska College of
Medicine
Clinical Professor, Creighton
University
School of Medicine
Department of Pediatrics
Creighton University School of
Medicine
Director of Patient Care Services,
Cardiology
Department of Cardiology
Children's Hospital & Medical Center
Omaha, Nebraska

Lary A. Latson, MD

Director, Pediatric International
Cardiology and Adult Congenital
Cardiology
Departments of Pediatric Cardiology
and Adult Cardiology
Joe DiMaggio Children's Hospital/
Memorial Health Care System
Hollywood, Florida

Peter C. Laussen, MBBS

Professor of Anesthesia
Harvard Medical School
Chief, Division of Cardiovascular
Critical Care
Department of Cardiology
Children's Hospital Boston
Boston, Massachusetts

Anthony Y. Lee, MD

Clinical Assistant Professor
Department of Pediatrics
The Ohio State University College of
Medicine
Attending Physician
Cardiothoracic Intensive Care Unit
Nationwide Children's Hospital
Columbus, Ohio

Mark B. Lewin, MD

Professor and Chief
Division of Pediatric Cardiology
Department of Pediatrics
University of Washington School of
Medicine
Heart Center Co-Director
Department of Cardiology
Seattle Children's Hospital
Seattle, Washington

D. Scott Lim, MD

Associate Professor
Department of Pediatrics and
Medicine
University of Virginia
Director of Cardiac Catheterization
Laboratory
Departments of Pediatrics and
Medicine
University of Virginia Health System
Charlottesville, Virginia

Angela E. Lin, MD

Associate Clinical Professor
Department of Pediatrics
Harvard Medical School
Staff Geneticist
Medical Genetics
MassGeneral Hospital for Children
Boston, Massachusetts

Frederick R. Long, MD

Clinical Professor

PREFACE

With this eighth edition of *Moss and Adams' Heart Disease in Infants, Children, and Adolescents*, the editors have attempted to garner updated and useful information from authors who are presently leading their various areas of our discipline. The field of genetics is ever expanding, as are arenas of care, diagnosis, and long-term evaluation. The responses from the authors reflect a careful approach to each chapter, and for that we are grateful. We have added chapters on quality of life, quality and safety, pharmacology, and research design that should prove useful to all of the readership, especially cardiology fellows who are about to take the sub-Board examination. Again, we thank authors who previously contributed to earlier editions as well as those who have joined authorship in this edition. It is they who deserve the appreciation of the readership of this text.

With the availability of an electronic version of the text, we have been able to move various appendices, the chapter on *The Development of Pediatric Cardiology*, and movies to

the online portion, leaving room for more text in the printed volumes. Additionally, we have included sub-Board-like questions for the various chapters in the electronic version. Hopefully this will be useful for those taking and recertifying the certifying examinations. It is important to note that present members of the sub-Board of Pediatric Cardiology did not participate in this component of the book. An editor who has not been a sub-Board member for some time (HDA) prepared these questions. The questions are not part of the sub-Board examination and have not been "lifted" from the examination, as Dr. Allen is far enough removed so as not to recall or know any questions on the present examination.

Hugh D. Allen, MD, FACC, FAAP, FAHA
David J. Driscoll, MD
Robert E. Shaddy, MD
Timothy F. Feltes, MD

ACKNOWLEDGMENTS

The authors deserve any positive credit for usefulness of this text.

The staff of Wolters Kluwer/Lippincott Williams & Wilkins has been fantastic. The advice, patience, and courage of Fran DeStefano; the organization, persistence, and attention to detail of Leanne Vandetty; and the recent addition of Julie Goolsby are most appreciated.

George Emmanouilides, MD, remains a wonderful and respected counselor for this text. Forrest Adams, MD, is still active and was a driving force from the beginning. Many thanks to each of you from all of us in the discipline.

I (HDA) am most grateful to my administrative assistant, Jayne Henry, for her attention to detail in translating my edits of the chapters.

TRIBUTE TO MOSS, ADAMS, & EMMANOUILIDES

Structure and Function of the Cardiovascular System

Cardiac Anatomy and Examination of Cardiac Specimens

William D. Edwards ■ Joseph J. Maleszewski

A fundamental understanding of cardiac anatomy forms the cornerstone of diagnostic pediatric cardiology and is a prerequisite for the proper interpretation of clinical cardiovascular imaging. In this chapter, cardiac anatomy is presented segmentally, with an emphasis on comparisons between analogous right-sided and left-sided structures. Although standard and commonly accepted anatomic terminology is used, anglicized forms are also provided in parentheses—for example, *crista terminalis* (terminal crest).

MEDIASTINUM

General Features

In keeping with their embryonic origins as midline structures, the heart and great vessels occupy the midthorax within the mediastinum. The anatomic borders of the mediastinum are as follows:

1. Anteriorly, the sternum and its adjacent ribs
2. Posteriorly, the vertebral column and its adjacent ribs
3. Laterally, the medial aspects of the parietal pleurae (pleurae)
4. Superiorly, the plane of the first rib
5. Inferiorly, the diaphragm

The mediastinum, in turn, is divided into four regions (Fig. 1.1). The heart, aortic arch, and descending thoracic aorta are located in the middle, superior, and posterior regions, respectively. Also located within the mediastinum are the esophagus, trachea, right and left main bronchi, thymus, lymph nodes, autonomic nerves, thoracic duct, and small vessels (including bronchial, esophageal, azygos, and hemiazygos).

Cardiac Size

The size of the heart relative to the thoracic cage varies with age. Radiographically, on a posteroanterior (PA) film, the normal cardiothoracic ratio is 60% or less for newborns and 50% or less in children and adults (Fig. 1.2). However, these ratios are applicable only for full respiratory inspiration, a condition that may be difficult to attain in newborns and infants. Accurate assessment of the great vessels by chest radiography also may be hampered by the overlying thymus.

Cardiac size also is proportional to body size and correlates better with body surface area and weight than with height. In well-conditioned athletes, with physiologic cardiac hypertrophy, heart weights may approach or slightly exceed the upper limits of normal. Heart weight varies with gender as well and, for the same body size, is greater in girls than in boys during infancy and childhood. By the time a body weight of 25 kg is achieved, however, heart weights are similar between genders, and beyond 35 kg of body weight, heart weights in boys exceed those in girls by about 10% (1). This trend continues throughout adult life and increases with body size, from 15% at 70 kg, to 20% at 100 kg, to 25% at 150 kg (2).

In general, the normal human heart is roughly the size of one's fist. In this regard, it is important to emphasize that a patient's heart size should be similar in size to the patient's fist, not the examiner's. This obvious fact easily can be forgotten when one is viewing cardiac images and not taking into account the size of the patient.

Cardiac Position

Within the mediastinum, the cardiac apex normally is directed leftward, anteriorly, and inferiorly, and this constitutes

Figure 1.1. Mediastinum, shown schematically. Viewed from a right lateral perspective, the mediastinum has four divisions.

levocardia. In newborns, the apical direction is more horizontal than in children or adults.

However, once the heart is removed from the chest, whether literally at autopsy or technically by projecting an image onto a video monitor, the extracardiac reference points are lost, and

orientation becomes a matter of convenience. Traditionally, photographs of cardiac specimens have been oriented with the apex down, and echocardiographic four-chamber images of the heart often are projected similarly. As a result, confusion has arisen concerning the true anatomic positions of the cardiac chambers and valves.

PERICARDIUM

General Features

The pericardium both covers the heart, as the epicardium, and surrounds it, as the parietal pericardium, much like a fluid-filled balloon covers a fist that is pressed into it. Between the two layers, within the pericardial sac, serous pericardial fluid (≤ 25 mL in adults) serves to lubricate the heart and allow its relatively friction-free movement within the chest. In addition, the parietal pericardium limits the diastolic dimensions of the heart.

Parietal Pericardium

The parietal pericardium represents a tough, flask-shaped sac that surrounds the heart and attaches along the great vessels, such that the ascending aorta and main pulmonary artery are intrapericardial (Fig. 1.3A). Similarly, the terminal 2 to 4 cm of the superior vena cava also is located within the pericardial

Figure 1.2. Cardiothoracic ratio. In posteroanterior chest radiograms, the relative size of the cardiac silhouette changes with age. **A:** Two-day-old newborn. **B:** Three-year-old child. **C:** Thirty-one-year-old man.

Figure 1.3. Parietal pericardium. A: With the anterior aspect of the parietal pericardium removed, the intrapericardial position of the great vessels is apparent. B: With most of the parietal pericardium excised, the pericardial reflection can be identified (arrows), as can the ligament of Marshall (arrowheads) and the transverse sinus (asterisk) (left lateral view). (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

sac, as are shorter lengths of the pulmonary veins and the inferior vena cava.

For patients with total anomalous pulmonary venous connection, the confluence of pulmonary veins is located within the pericardial sac behind the heart. In contrast, the right and left pulmonary arteries and the ductus arteriosus are extrapericardial structures, and surgical procedures restricted to these vessels do not require a pericardial incision.

The parietal pericardium consists of an outer fibrous layer and an inner serous layer of mesothelial cells. The fibrous layer is densely collagenous and is ≤ 1 mm thick in adults. Its outer surface also normally contains variable amounts of adipose tissue, especially near the diaphragm, that can cause apparent thickening of the pericardium, as well as contribute to the cardiac silhouette radiographically.

Because the fibrous pericardium contains little elastic tissue, it cannot distend acutely. Consequently, the rapid accumulation of as little as 200 mL of pericardial fluid in adults generally produces hemodynamic features of cardiac tamponade. However, in the setting of chronic enlargement of the heart, as occurs with normal body growth or with cardiac dilation, stretching and growth of the parietal pericardium do take place to accommodate the increasing cardiac volume. Such growth is capable of accommodating >1 L of chronic pericardial effusion.

Visceral Pericardium (Epicardium)

The visceral pericardium, or epicardium, covers the heart and the intrapericardial portions of the great vessels. It consists of a delicate lining of mesothelial cells and the subjacent adipose tissue, coronary vessels, and nerves along the surface of the heart. Adipose tissue tends to accumulate within the atrioventricular (AV), interventricular, and interatrial grooves (sulci) and along the acute margin of the right ventricle and the coronary branches. Prominent tags of fat cover the origins of the coronary arteries, between the aorta and the atrial appendages. With increasing age, epicardial fat increases in amount and may infiltrate into the atrial septum, particularly within the limbus of the fossa ovalis.

Because the heart must be compliant enough to enlarge during ventricular diastole and to contract during systole, the

normal visceral pericardium has no dense fibrous component. Even so, it does have appreciable mechanical strength, as evidenced by the fact that, following coronary interventions complicated by arterial perforation, the overlying epicardium readily withstands coronary blood pressure and thereby deters rupture into the pericardial sac.

Pericardial Reflection

The junction between the parietal and visceral layers occurs along the great vessels and is known as the pericardial reflection. That portion involving the great veins forms the oblique sinus, a cul-de-sac (shaped like an inverted U) along the posterior aspect of the left atrium. Between the great arteries, anterosuperiorly, and the atrial walls, posteroinferiorly, is a tunnel-shaped structure, the transverse sinus (Fig. 1.3B). Nearby, the ligament of Marshall represents the embryonic remnant of a left superior vena cava.

Intraoperatively, in the setting of pulmonary atresia, if a remnant of the hypoplastic or atretic main pulmonary artery exists, it will be found along the ascending aorta, anterosuperior to the transverse sinus. Conversely, a persistent left superior vena cava will abut the left pulmonary artery, posterior to the transverse sinus.

Following operative procedures that include an anterior pericardiotomy, the development of fibrinous pericarditis is the rule and may be accompanied by a friction rub. As healing takes place, fibrin is replaced by fibrovascular granulation tissue, from which oozing of blood may occur as small vessels are eroded by repeated contact between the parietal and visceral layers with each heartbeat. For this reason, the pericardium generally is left open postoperatively so that accumulations of blood or fluid can be drained into one of the pleural cavities and removed through a chest tube.

Within a few days, however, the raw and inflamed surfaces generally begin to adhere to the overlying sternum, effectively closing the pericardium. When this occurs, oozing of blood from the pericardial surfaces can result in the insidious development of postoperative cardiac tamponade. Furthermore, in supine patients, localized accumulations of blood within the oblique sinus can produce isolated left

atrial tamponade, which can be readily detected by bedside echocardiography.

Over time, organization of fibrinous exudates often results in the development of diffuse fibrous adhesions between the parietal pericardium and the epicardial surface, although progression to constriction is rare. However, fibrous adhesions may increase the risk of subsequent cardiac operations by obscuring the locations of epicardial coronary arteries or, when dissected free, by causing appreciable intraoperative bleeding while the patient is heparinized.

EXTERNAL TOPOGRAPHY

General Features

The AV groove (sulcus) defines the plane of the base of the heart, which contains the four major cardiac valves. The anterior and inferior interventricular grooves indicate the plane of the underlying ventricular septum. Externally, the two ventricles are similar in size and the atria are appreciably smaller than the ventricles, even though all four internal chamber volumes are similar. Along the surface of the heart, the right and circumflex coronary arteries travel in the right and left AV grooves, respectively, and the left anterior and posterior descending coronary arteries course along the anterior and inferior interventricular grooves, respectively. Thus, by external inspection alone, surgeons and pathologists can assess the location of the coronary arteries and the presence of hypoplastic or dilated chambers.

Base–Apex Characteristics

The ventricles, being roughly conical, have a base (at the base of the heart) and an apex. The base–apex direction (or axis) for both ventricles is leftward, anterior, and inferior, and the two directions are roughly parallel. However, in crisscross hearts, the ventricular apical directions cross and are often perpendicular.

Because the left base–apex length normally is greater than that of the right, the left ventricular apex generally forms the

true apex of the heart. However, the right ventricle may form the cardiac apex when the left ventricle is hypoplastic or when the right ventricle is dilated. Rarely, the interventricular groove is quite deep apically and results in a heart with a bifid apex.

The cardiac apex normally is located along the left mid-clavicular line at the fourth or fifth intercostal space. Clinically, the point of maximal impulse usually corresponds to the anteroapical region of the left ventricle rather than to the true cardiac apex.

External Landmarks

The junction between the anterior and inferior free walls of the right ventricle forms a sharp angle known as the acute margin, the basal aspect of which delineates the right shoulder of the heart. Analogously, the rounded lateral wall of the left ventricle forms an ill-defined obtuse margin, and its basal aspect represents the left shoulder of the heart. Thus, coronary vessels supplying this region are known as obtuse marginal branches of the circumflex artery. Along the inferior (diaphragmatic) aspect of the heart, the AV, interventricular, and interatrial grooves form a cross-shaped intersection called the crux cordis (crux of the heart).

Chambers and Great Vessels

To properly interpret the various cardiac imaging modalities, one must understand not only the normal size and shape of the cardiac chambers and great vessels but also their relative positions three-dimensionally (Fig. 1.4). In this regard, only the right atrium is anatomically named correctly. It is truly a right lateral chamber, whereas the left atrium lies in the midline posteriorly and is not a left-sided structure. The right ventricle is a right anterior chamber, and the left ventricle is a left posterior structure. Although not striking, the atria are located slightly superiorly relative to the ventricles. Positionally, the aorta arises posteriorly, inferiorly, and to the right of the main pulmonary artery. In patients with congenitally malformed hearts, the relative sizes and positions of the cardiac chambers and great vessels may vary considerably from normal.

Figure 1.4. External cardiac anatomy. The heart and great vessels are shown from the anterior (A), posterior (B), right lateral.

Figure 1.4. (Continued) (C), left lateral (D), superior (E), inferior (F), right anterior oblique (G), and left anterior oblique (H) anatomic perspectives, as indicated for each view. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 1.5. Systemic veins, shown schematically. **A:** The systemic veins include the superior and inferior venae cavae and their tributaries. **B:** The portal circulation drains the abdominal digestive system and the spleen. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

GREAT VEINS

Superior Vena Cava

The internal jugular and subclavian veins merge to form brachiocephalic (or innominate) veins bilaterally (Fig. 1.5). Their junctions usually are guarded by venous valves (3). The brachiocephalic veins enter the mediastinum at the level of the first rib, posterior to the sternoclavicular joint. The left brachiocephalic or innominate vein is two to three times the length of its right-sided counterpart and lies along the anterosuperior aspect of the aortic arch and its brachiocephalic branches.

Each innominate vein receives internal mammary (thoracic) and pericardiophrenic veins, and the left also receives the inferior thyroidal vein.

Both brachiocephalic veins merge to form the superior vena cava, which lies just anteriorly to the right pulmonary artery and against the posterolateral aspect of the ascending aorta. The azygos vein arches over the right bronchus and empties into the superior vena cava posteriorly. The superior vena cava, as a right lateral structure, contributes to the right superior border of the radiographic frontal cardiac silhouette (Fig. 1.6). Approximately one-third to one-half of its length is intrapericardial as it approaches the right atrium.

Figure 1.6. Heart and great vessels. **A:** The borders of the frontal cardiac silhouette are demonstrated on a chest radiogram. **B:** An anterior view of a cardiac specimen is shown, for comparison with A. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

The right internal jugular vein, right brachiocephalic vein, and superior vena cava provide a short and relatively straight intravascular route to the right atrium and tricuspid orifice that may be used for obtaining endomyocardial biopsy specimens from the right ventricle. Subclavian veins often are used for the placement of transvenous pacemaker leads, and both the subclavian and internal jugular veins are used for the insertion of pressure-monitoring catheters. Indwelling catheters and pacemaker leads can become coated with shallow thrombus, particularly at sites of contact with vascular walls, which may become sources of embolization or infection.

Inferior Vena Cava

The inferior vena cava receives systemic venous drainage from the legs, retroperitoneal viscera, and the portal circulation (Fig. 1.5). Because the veins from the abdominal digestive system drain through the liver, ingested substances are metabolized before they gain access to the remainder of the body. The suprahepatic portion of the inferior vena cava is only a few centimeters in length and, after traversing the diaphragm, joins the inferior surface of the right atrium.

The ostium of the inferior vena cava is guarded by a diminutive crescent-shaped flap of tissue, the eustachian valve. Although generally small, this valve of the inferior vena cava can become so large that it produces a double-chambered right atrium (cor triatriatum dexter) and can be so obstructive to the tricuspid valve inflow that underdevelopment of the right ventricle results.

Interestingly, the vertebral venous plexus does not directly join the inferior vena cava. Rather, it drains into the intracranial, intercostal, lumbar, and lateral sacral veins, as well as into the portal system via the rectal venous plexus. Accordingly, infections or metastases may spread to the vertebral bodies or central nervous system through this vascular network.

Coronary Sinus

The coronary sinus travels in the left AV groove and receives not only the great cardiac vein but also the posterior, middle, and small cardiac veins. It empties into the right atrium near the atrial septum and the orifice of the inferior vena cava. During electrophysiologic studies in patients with the Wolff-Parkinson-White preexcitation syndrome and left-sided bypass tracts, a multielectrode catheter can be positioned within the coronary sinus and great cardiac vein, adjacent to the mitral valve ring, to localize the aberrant conduction pathways. During cardiac operations, cardioplegic solution may be administered retrogradely into the coronary sinus.

The coronary sinus ostium is guarded by a crescent-shaped valve, the thebesian valve. A commissure exists between the valves of the coronary sinus and the inferior vena cava. From this commissure, a small cord, the tendon of Todaro, travels just beneath the endocardium and inserts into the membranous septum. Rarely, an unroofed coronary sinus drains directly into the left atrium, or the coronary sinus ostium is atretic.

The valves of the inferior vena cava and coronary sinus both are derived from the embryonic right venous valve. When either is enlarged and fenestrated, the term Chiari net (or network) may be applied.

Pulmonary Veins

Superior (upper) and inferior (lower) pulmonary veins from each lung join the posterolateral aspects of the left atrium. Owing to the midline nature of the left atrium, the right-sided

veins are similar in length to their left-sided counterparts. As a variation of normal, a middle lobe vein from the right lung may enter the left atrium separately rather than first joining the upper lobe vein. In other cases, the upper and lower pulmonary veins, particularly from the left lung, can merge and join the left atrium as a single vein.

The right and left lower pulmonary veins each travel along the inferior aspect of the corresponding main bronchus. In contrast, the two upper veins each course anteriorly to their respective bronchus and, at the pulmonary hilum, lie anteriorly to the right intermediate and left main pulmonary arteries. Thus, because the upper pulmonary veins travel anteriorly and the pulmonary arteries travel posteriorly (moving from the heart to the hilus), the veins are posterior to the arteries at the level of the left atrium but lie anteriorly to the arteries at the level of the pulmonary hilum.

Interestingly, the media of the pulmonary veins, within 1 to 3 cm of the left atrium, contain myocardial cells rather than smooth muscle cells. Consequently, these regions can function as sphincters during atrial systole and thereby minimize retrograde blood flow back into the lungs. These venous myocytes also can be the nidus for atrial fibrillation. Because the pulmonary veins normally are thin walled and distended under low pressure, they are prone to extrinsic compression either by a native structure, such as thrombus or neoplasm, or by synthetic materials, such as a conduit or surgical hemostatic packing material.

ATRIA

General Features

The right and left atria serve as receiving chambers for blood returning from the systemic and pulmonary venous systems, respectively. They also have an endocrine function, particularly the right atrium. In the setting of right atrial dilation or congestive heart failure, atrial natriuretic peptide is released from secretory granules within myocytes, as part of the cardiovascular system for sodium and body fluid homeostasis.

Right Atrium

The right atrium is a right lateral chamber that, along with the venae cavae, forms the right lateral border of the radiographic frontal cardiac silhouette (Fig. 1.6). It receives blood from the two venae cavae, coronary sinus, and numerous small thebesian veins, and it expels blood across the tricuspid valve and into the right ventricle. Structurally, the right atrium consists of free-wall and septal components.

Free Wall

Internally, the free wall has a smooth posterior region and a more muscular anterior region (Fig. 1.7). The posterior aspect receives the two venae cavae and has a vein-like appearance, in keeping with its embryologic origin from the sinus venosus. In contrast, the anterior aspect exhibits a muscular wall and a large pyramidal appendage. A prominent C-shaped ridge of muscle, the crista terminalis, serves to separate the two regions and forms one of the tracts for internodal conduction.

Numerous pectinate muscles arise from the terminal crest and travel as parallel ridges along the anterior aspect of the free wall. *Pectinatus* is Latin for comb, and the crista terminalis and pectinate muscles may be likened to the backbone and teeth of a comb, respectively. An irregular arrangement of pectinate muscles also is found within the atrial appendage, and, as a result, atrial pacemaker leads can be lodged readily in

Figure 1.7. Comparison of right and left atria. **A:** Opened right atrium. Two arrow-shaped probes show that the superior vena cava is directed toward the tricuspid orifice and the inferior vena cava is directed toward the fossa ovalis. **B and C:** Atrial septum. A white probe in the patent foramen ovale passes between the limbus and valve of the fossa ovalis in the right atrium (**B**) and exits through the ostium secundum in the left atrium (**C**). **D and E:** Atrial free walls. The right atrial wall (**D**, viewed from a left lateral perspective) contains a crista terminalis and pectinate muscles, whereas the left atrial wall (**E**, viewed from an anterior perspective) contains neither of these structures. **F:** The interatrial and AV septa are demonstrated in a four-chamber slice of the heart. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

this area. The right atrial appendage rests against the ascending aorta and overlies the proximal right coronary artery.

When right atrial enlargement is associated with stasis to blood flow, thrombus may form between the pectinate muscles, particularly within the appendage. Transvenous pacemaker leads and intracardiac catheters often produce linear contact lesions at the cavoatrial junction, and these usually become lined by shallow mural thrombi.

It is important to note that the atrial wall between the ridges of pectinate muscles is generally <1 mm thick and can be perforated by catheters and pacemaker leads. Although the posterior half of the free wall (derived from the sinus venosus) is also only about 1 mm thick, it has a thicker endocardium and, therefore, is less prone to perforation. In adolescents and adults, the pectinate muscles are 2 to 4 mm thick, and the crista terminalis may achieve a thickness of 3 to 6 mm.

Septum

When viewed from the right, the septum has an interatrial component (between the right and left atria) and an AV component (between the right atrium and left ventricle). The interatrial portion is relatively small, and its most prominent feature is the fossa ovalis (4). This consists of a horseshoe-shaped muscular rim—the limbus, which forms a pathway

for internodal conduction—and a central sheet of thin fibrous tissue—the valve of the fossa ovalis (Fig. 1.7). In adolescents and adults, the limbus averages 4 to 8 mm in thickness, and the valve is about 1 mm thick. Embryologically, the valve of the fossa ovalis represents the first septum that develops (septum primum), and the limbus represents the second septum that forms (septum secundum).

During fetal and neonatal life, the valve of the fossa ovalis represents a paper-thin, delicate, translucent membrane. As such, it readily is torn (or stretched) during balloon atrial septostomy procedures. With increasing age, however, the progressive deposition of collagen and elastin produces a thicker, tougher, opaque valve (5). As a result, transseptal procedures may be more difficult in older children, adolescents, and adults.

In contrast to the fossa ovalis, the foramen ovale represents a potential passageway between the two atria. It courses between the anterosuperior aspect of the limbus and the valve of the fossa ovalis and then through a natural valvular perforation, the ostium secundum, and into the left atrium (Fig. 1.7). Although the foramen ovale is patent throughout fetal life, it functionally closes soon after birth, as left atrial pressure begins to exceed that in the right atrium, and the valve of the fossa ovalis becomes pressed against the limbus, thereby effectively closing the foramen.

In approximately two-thirds of individuals, the foramen ovale closes permanently during the first year of life, as fibrous tissue seals the valve to the limbus of the fossa ovalis. Thus, in about one-third of infants, children, and adolescents, this flap valve is not sealed (patent foramen ovale) and closes only when the pressure in the left atrium exceeds that in the right atrium. During the Valsalva maneuver, for example, a small right-to-left shunt can be detected echocardiographically in persons with a patent foramen ovale. In adolescents and adults, the foramen ovale ranges from 2 to 10 mm in maximal potential diameter, with a mean size of 5 to 6 mm (6).

In the setting of pronounced atrial dilation, the atrial septum can be stretched to such an extent that the limbus no longer covers the ostium secundum, resulting in a valvular-incompetent patent foramen ovale—an acquired atrial septal defect. In contrast, fenestrations of the valve are the most common cause of congenital atrial septal defects. Excessive valve tissue may undulate during the cardiac cycle and form an aneurysm of the fossa ovalis (see Chapter 28).

Because the tricuspid valve annulus attaches to the septum lower (more apically) than the mitral annulus, septal myocardium is interposed between the right atrium and the left ventricle. This constitutes the AV septum (Fig. 1.7). Although this is primarily a muscular septum, on average 10 mm thick in adults, it also contains a membranous portion that is only about 1 mm thick. The AV portion of the membranous septum is located at the anterosseptal tricuspid commissure (when viewed from the right side of the heart) and beneath the right posterior aortic commissure (as seen from the left side).

The AV septum corresponds to the triangle of Koch, an important anatomic surgical landmark because it contains the AV node and the proximal (penetrating) portion of the AV (His) bundle. Thus, during tricuspid annuloplasty procedures, care must be taken to avoid injury to the conduction system. When defects occur in the muscular AV septum, the mitral annulus usually drops to the same level as the tricuspid annulus, so that the defect becomes primarily interatrial, and the AV conduction tissues are displaced inferiorly.

Finally, a medial portion of the free wall lies against the right aortic sinus, which bulges somewhat into the atrial cavity as the torus aorticus (aortic bulge). This protuberance is bordered by the limbus of the fossa ovalis, the ostium of the appendage, the tricuspid annulus, and the AV septum. During transseptal procedures, care must be taken to stay within the confines of the valve of the fossa ovalis to avoid perforation along the aortic protuberance, which could result in trauma to the adjacent aortic root or coronary arteries. Rarely, atrial septal defect closure devices have eroded into the aortic root (see Chapter 13).

Because of hemodynamic streaming within the right atrium during intrauterine life, poorly oxygenated blood from the superior vena cava is directed toward the tricuspid orifice, whereas well-oxygenated placental blood within the inferior vena cava is directed by the eustachian valve toward the foramen ovale and into the left atrium. Consequently, the most oxygenated blood in the fetal circulation travels, via the left side of the heart, to the coronary arteries, upper extremities, and the rapidly developing central nervous system. Throughout postnatal life, this orientation of the venae cavae is maintained (Fig. 1.7). As a result, transseptal procedures are performed more easily via the inferior vena cava, in contrast to right ventricular biopsies, which are performed more readily by a superior vena caval approach.

Left Atrium

The left atrium is a midline posterior chamber that receives pulmonary venous blood and expels it across the mitral valve

and into the left ventricle. By virtue of its posterior location, the body of the left atrium does not contribute to the borders of the radiographic frontal cardiac silhouette. However, the left atrial appendage, when enlarged, may produce a bulge along the left cardiac border, between the left ventricle and the left pulmonary artery.

Interposed between the left atrium and the vertebral bodies are the esophagus, to the right, and the descending thoracic aorta, to the left. Furthermore, the bifurcated pulmonary artery and left bronchus travel along the superior aspect of the left atrium, and the left and posterior aortic sinuses may indent the atrial wall as the aortic protuberance (torus aorticus). During transesophageal echocardiography, the transducer is placed close to the left atrium and provides excellent visualization of the atria, AV valves, and great vessels.

In the setting of left atrial dilation, the left bronchus is pushed upward, as can be seen radiographically, and the esophagus is displaced rightward. When a left superior vena cava persists, the coronary sinus into which it drains generally is quite dilated, in some cases indenting the left atrial wall, and should not be mistaken echocardiographically for the descending thoracic aorta. As on the right side, the left atrium consists of a free wall and a septum.

Free Wall

The free wall includes a dome-shaped body, which receives the pulmonary veins, and a finger-like appendage. These two regions are separated externally by the left atrial coronary vein and ligament of Marshall and internally by the ostium of the appendage. The left atrial body, although 1 to 3 mm thick and infiltrated by cardiac myocytes, is derived embryologically from the common pulmonary vein and internally maintains a smooth vein-like appearance. The endocardium is opaque and gray-white, owing to the deposition of collagen and elastin, and is thicker and less compliant than that in the other three chambers.

The left atrial appendage rests along the left AV groove and covers the proximal circumflex coronary artery and, in some individuals, the left main coronary artery. The appendage contains numerous small pectinate muscles, has a variable number of lobes or blind-ended pouches, and is tortuous and may fold on itself. Outside the appendage, the body of the left atrium contains no pectinate muscles, and there is no crista terminalis.

As the left upper pulmonary vein joins the left atrium, an infolded ridge often forms where the ostium of the pulmonary vein is contiguous with that of the atrial appendage. This should not be mistaken as a partial form of cor triatriatum (triatrial heart).

Septum

When viewed from the left, the septum is entirely interatrial. Along its anterosuperior border, the valve of the fossa ovalis contains one or more fenestrations, representing the embryologic counterpart of the ostium secundum. If a probe passed through the fenestrations enters the right atrium, the foramen ovale is considered patent. Neither the limbus of the fossa ovalis nor the AV septum is visible from within the left atrium. Several small thebesian veins drain directly into the left atrial cavity, particularly along the septum.

Comparison of the Atria

With regard to the atrial septum, the limbus of the fossa ovalis is a feature of the right atrium, and the ostium secundum is characteristic of the left atrium (Fig. 1.7). The free wall of the right atrium contains the crista terminalis and pectinate muscles, whereas that of the left atrium does not (Table 1.1). Moreover, the right atrial appendage is large and pyramidal,

TABLE 1.1 Comparison of Right-Sided and Left-Sided Anatomic Fractures of Cardiac Segments

Right Atrium	Left Atrium
Limbus of fossa ovalis (limb of oval fossa)	Ostium secundum
Large pyramidal appendage	Small finger-like appendage
Crista terminalis (terminal crest)	No crista terminalis
Pectinate muscles	No pectinate muscles
Receives venae cavae and coronary sinus ^a	Receives pulmonary veins ^a
Tricuspid Valve	Mitral Valve
Low septal annular attachment	High septal annular attachment
Septal cordal attachments	No septal cordal attachments
Triangular orifice (midleaflet level)	Elliptical orifice (midleaflet level)
Three leaflets and commissures	Two leaflets and commissures
Three papillary muscles	Two large papillary muscles
Empties into right ventricle	Empties into left ventricle
Right Ventricle	Left Ventricle
Tricuspid–pulmonary discontinuity	Mitral–aortic continuity
Muscular outflow tract	Muscular–valvular outflow tract
Septal and parietal bands	No septal or parietal band
Large apical trabeculations	Small apical trabeculations
Coarse septal surface	Smooth upper septal surface
Crescentic in cross sections ^a	Circular in cross section ^a
Thin free wall (3–5 mm) ^a	Thick free wall (12–15 mm) ^a
Receives tricuspid valve	Receives mitral valve
Pulmonary Valve	Aortic Valve
Empties into main pulmonary artery	Empties into ascending aorta

^aVariable feature.

whereas the left atrial appendage is smaller and finger-like. Although the superior vena cava and the pulmonary veins can anomalously join the contralateral atrium, the inferior vena cava almost invariably joins the morphologic right atrium.

Thus, the distinguishing features of a morphologic right atrium are the limbus of the fossa ovalis, connection of the inferior vena cava, and a large pyramidal appendage. The limbus can be detected with four-chamber imaging, and the course of the inferior vena cava and the morphology of the atrial appendage can be assessed by either invasive or noninvasive imaging. Identification of the crista terminalis and pectinate muscles is possible by direct inspection at operation or autopsy but not consistently by imaging procedures.

ATRIOVENTRICULAR VALVES

General Features

The AV valves serve to maintain unidirectional blood flow and to electrically separate the atria and ventricles. Each valve has five components. The annulus, leaflets, and commissures form the valvular apparatus, and the chordae tendineae (tendinous cords) and papillary muscles form the tensor apparatus.

The annulus of each valve is somewhat saddle shaped rather than being truly planar and represents an ill-defined

ring of fibrous tissue from which the leaflets arise. Although the mitral annulus is a continuous ring of collagen, the tricuspid annulus is not and exhibits loose connective tissue at the points of annular discontinuity. Consequently, ventricular dilation leads more readily to annular dilation of the tricuspid valve than that of the mitral valve. During the first two decades of life, valvular growth correlates better with age than with body height, weight, or surface area (1).

Leaflets represent delicate flaps of connective tissue. Owing to direct cordal insertions along their leading edges, the free edges have a serrated appearance. Tendinous cords also insert along the ventricular aspect of each leaflet (the valve pocket or undersurface) and thereby support the leaflet during ventricular systole. On the atrial aspect, the closing edge represents an ill-defined junction between the thinner body (or clear zone) and the thicker contact region (or rough zone) of the leaflet. During valve closure, apposing leaflets contact one another along the surfaces between the free and closing edges (Fig. 1.8). In about 50% of fetuses and infants, blood cysts occur as small (<3 mm) purple nodules along the contact surfaces of the mitral and tricuspid valves and generally disappear within 1 year (7).

Microscopically, each leaflet exhibits two major layers. A fibrous layer (fibrosa) forms the strong structural backbone of the valve and is continuous from the annulus proximally to the sites of cordal insertion distally. In contrast, the spongy layer (spongiosa) acts as a shock absorber and becomes prominent along the contact regions of each leaflet. Because the leaflets are

thin and compliant and are attached only at the annulus and papillary muscles, rapid opening and closure of the valve is possible.

A commissure represents the site along a valve annulus where two leaflets meet. Commissures always have an underlying papillary muscle and a fan-like array of tendinous cords that attach to both leaflets, in contrast to congenital clefts, which have neither. Although each leaflet has two major commissures, it also may be divided further into several regions, or scallops, by minor commissures, each of which has a small underlying papillary muscle.

The tendinous cords act as strong fibrous guy wires to anchor and support the leaflets. Accordingly, they restrict excessive valvular excursion during ventricular systole and prevent valvular prolapse into the atrium. Because a cord generally branches several times, more than 150 cords normally insert into the free edge or ventricular aspect of each valve, which tends to distribute the systolic force of ventricular blood evenly along the undersurface of each leaflet (8,9). If the tendinous cords are malformed, weakened, or insufficient in number, a portion of the leaflet can begin to bulge and prolapse, leading to valvular regurgitation. This commonly occurs not only with myxomatous valves but also with common AV valves and at least one of the two AV valves in a double-inlet left ventricle (10).

Papillary muscles can be single, multiheaded, or a fused group. By being positioned directly beneath a commissure and by receiving tendinous cords from two adjacent leaflets, a papillary muscle tends to pull its two leaflets toward each other during ventricular systole, thereby facilitating valve closure. Ventricular contraction also contributes to valve closure by decreasing the annular dimension and shortening the base–apex length of the chamber. Thus, papillary muscle ischemia or ventricular dilation may produce valvular regurgitation, as can be seen with the tricuspid valve after severe birth asphyxia or in the setting of persistent pulmonary hypertension of the newborn.

Tricuspid Valve

Because of the normal rightward bowing of the ventricular septum, the tricuspid annulus is shaped like a reversed D when viewed from its ventricular aspect (Fig. 1.8). However, at midleaflet level, the orifice becomes triangular. Annular dimensions vary with the cardiac cycle, decreasing by about 20% in circumference and 33% in area during systole, owing to contraction of the right ventricular myocardium (11). The plane of the tricuspid annulus faces toward the right ventricular apex.

Figure 1.8. Comparison of right and left AV valves. **A:** The tricuspid valve normally has three leaflets. The membranous septum is located along its annulus (*dashed line*), at the anterosseptal commissure (*arrow*). **B:** The mitral valve has two leaflets, with papillary muscles beneath each commissure. **C and D:** In short-axis views, the tricuspid orifice is shaped like a reversed D at the annular level (**C**) and like a triangle at the midleaflet level (**D**). In contrast, the mitral orifice is elliptical at both levels. As shown in **D**, the anterior leaflet (*arrow*) of each valve is a midcavitary structure that divides its ventricle into inflow and outflow regions. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Whereas the septal and posterior leaflets lie against the ventricular septum and inferior wall of the right ventricle, respectively, the anterior leaflet forms a prominent intracavitary curtain that partially separates the inflow and outflow tracts. The anterior leaflet is the most mobile of the three, and the septal leaflet, by virtue of its numerous direct cordal attachments along the ventricular septum, is the least mobile. The relative sizes of the three leaflets vary appreciably from person to person (9).

Among the three papillary muscles, the anterior muscle is the largest and most well formed. It originates from the acute margin of the right ventricle, may be single or bifid, and provides cordal insertions to the anterior and posterior leaflets. The posterior papillary muscle arises from the inferior wall near the septum, and the posterior and septal leaflets receive cords not only from this small muscle but also from accessory papillary muscles and trabeculations. The medial papillary muscle (also called the papillary muscle of the conus or the muscle of Lancisi) emanates along the superior aspect of the septal band, at the level of the membranous septum, and has cordal attachments to the septal and anterior leaflets. Although prominent in infants and children, it commonly merges with the septal band and becomes small or absent by adulthood.

Of the three commissures, the anteroseptal is the most variable. It traverses the midportion of the membranous septum, dividing it into AV and interventricular regions. Leaflet tissue is deficient at this commissure in about 10% of hearts, and the membranous septum fills the 1- to 7-mm gap between the anterior and septal leaflets (12). This commissure is also characteristically deficient in partial AV septal defects.

Mitral Valve

The mitral annulus changes shape during the cardiac cycle, from circular in diastole to elliptical during systole. However, at the midleaflet level, the diastolic orifice is elliptical or football shaped. The annular circumference and area also decrease by approximately 15% and 25%, respectively, during ventricular systole (13). Unlike the tricuspid annulus, the mitral annulus is directed more toward the midportion of the septum than toward the apex. Although the entire annular circumference connects to the overlying left atrium, only a C-shaped portion attaches to the underlying left ventricular free wall. The remaining 30% of the annulus is intracavitary, is attached to the anterior mitral leaflet, and is continuous with the aortic valve annulus.

Therefore, the anterior mitral leaflet, like the anterior tricuspid leaflet, forms an intracavitary curtain that partially separates the inflow and outflow tracts (Fig. 1.8). However, unlike its right-sided counterpart, it actually forms part of the outflow tract and may contribute to subaortic obstruction in such disorders as hypertrophic cardiomyopathy. Whereas the anterior leaflet is semicircular, the posterior leaflet is rectangular and usually is subdivided by minor commissures into three or more semicircular scallops. Only the mitral valve has just two leaflets; the other three valves each have three leaflets or cusps.

Interestingly, the surface areas of the anterior and posterior leaflets are almost identical and together provide nearly twice the area needed to close the systolic annular orifice (14). However, because some folding and puckering of leaflet tissue, as well as appreciable surface area for contact between leaflets, are needed to ensure a competent seal, the mitral leaflets are not as redundant as they might first appear.

The mitral valve has two major commissures, beneath which are located the two major papillary muscles, anterolateral and posteromedial. In addition to the usual tendinous cords, two thick and prominent strut cords, one from each papillary muscle, attach to the ventricular aspect of the

anterior leaflet and offer additional support (15). In about 50% of subjects, cordal structures known as left ventricular pseudotendons arise from a papillary muscle and insert onto either the septum or the opposite papillary muscle. In contrast, attachment of cords from a mitral leaflet to the ventricular septum is distinctly abnormal and is usually associated with AV septal defects or straddling mitral valves.

Both papillary muscles originate from the left ventricular free wall and can have thicknesses similar to those of the ventricular wall. They occupy the middle third of the left ventricular base–apex length, not only in normal hearts but also in hypertrophied and dilated hearts. In the setting of hypertrophic cardiomyopathy, the mitral papillary muscles may be particularly prominent and occupy a substantial portion of the potential volume of the left ventricular chamber.

The anterolateral papillary muscle commonly is single with a midline groove and usually has a dual blood supply from the left anterior descending and circumflex coronary arteries. In contrast, the posteromedial papillary muscle generally is multiple or else bifid or trifid, and it most commonly is nourished solely by the right coronary artery. The anterolateral muscle usually is larger and extends closer to the mitral annulus than the posteromedial muscle.

Comparison of Atrioventricular Valves

The tricuspid valve has three leaflets, commissures, and papillary muscles, whereas the mitral valve has only two of each. Other differences also exist that may be of clinical use (Fig. 1.8 and Table 1.1).

From a practical standpoint, identification of the lower septal insertion of the tricuspid annulus, as distinct from the mitral, can be assessed with four-chamber images (Fig. 1.7F) in both normal and malformed hearts. Exceptions include partial AV septal defects and double-inlet ventricles, in which the two valves achieve the same annular level. Along the septum, the distance between the mitral and tricuspid insertions is <0.8 cm/m² body surface area in normal hearts and is greater than this in the Ebstein malformation (16).

The insertion of numerous cords directly onto the septum is a reliable distinguishing feature of the tricuspid valve. Finally, the tricuspid valve virtually always connects to a morphologic right ventricle, whereas the mitral valve connects to a morphologic left ventricle. Differences also exist between the two valves with regard to annular size and orifice shape.

VENTRICLES

General Features

Normally, a ventricle receives blood through an AV valve from an atrium and pumps it across a semilunar valve into a great artery. Because all four major cardiac valves lie in the same plane, at the base of the heart, blood entering and exiting a ventricle follows a V-shaped course. During ventricular systole, both the base–apex length and the short-axis diameter decrease and not only expel blood from the chamber but also assist closure of the AV valve by decreasing its annular size.

Heart weight, which roughly corresponds to ventricular mass, is related to body surface area or weight for all age groups (1,2). During the first two decades of life, thicknesses of the right and left ventricular free walls and the ventricular septum correlate better with age than with body size. In normal hearts, the ratio between ventricular septal and left ventricular free-wall thicknesses is 1.1 (range 0.8 to 1.4), and the ratio between left and right ventricular thicknesses is 3

Figure 1.9. Comparison of right and left ventricles. **A:** In cross section, the right ventricle is crescent shaped, the left ventricle is circular, and the wall thickness of the left ventricle is three to four times that of the right ventricle. **B:** The fetal heart (*to the left*) exhibits prominent right ventricular hypertrophy, whereas by the age of 3 months, the infant's heart (*to the right*) shows regression of hypertrophy. **C:** The right ventricle receives a tricuspid valve, has prominent anteroapical trabeculations, and has a muscular outflow track that separates the tricuspid and pulmonary valves. The parietal and septal bands and the outlet septum form the crista supraventricularis (supraventricular crest). **D:** The left ventricle, in contrast, receives a mitral valve, has shallow apical trabeculations, and exhibits direct continuity between the mitral and aortic valves. **E:** The membranous septum is divided into AV and interventricular components by the septal tricuspid leaflet (*arrow*). (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

(range 2 to 5). Autopsy measurements of wall thickness tend to correspond to end-systolic rather than end-diastolic dimensions (17).

It is important to note that the right ventricle in fetuses and neonates differs from that in older persons. During fetal life, the presence of a patent ductus arteriosus is associated with equalization of aortic and pulmonary artery pressures and a state of physiologic pulmonary hypertension. Thus, during fetal and neonatal life, right ventricular hypertrophy is evident and the thickness of the right ventricle is similar to that of the left (Fig. 1.9).

Right Ventricle

As a right anterior chamber, the right ventricle normally does not contribute to the radiographic frontal cardiac silhouette. The anterior and inferior surfaces of its free wall merge along the acute margin of the heart and form an angle of 45 to 75 degrees. This, along with rightward bowing of the ventricular septum, results in a crescent-shaped chamber in the short-axis view. Conditions such as pulmonary hypertension that impose a pressure or volume overload on the right ventricle and cause

its hypertrophy and dilation may be attended by straightening of the septum so that both ventricles become D-shaped on cross section. In extreme cases, such as an Ebstein anomaly or total anomalous pulmonary venous connection, leftward bowing of the septum can result not only in a reversal in ventricular short-axis shapes but also in possible obstruction of the left ventricular outflow tract.

Anatomically, the right ventricle can be divided into inlet, trabecular, and outlet regions. This concept of a tripartite chamber correlates well with the embryologic development of the right ventricle. The inlet portion is associated with the tricuspid valve, and its border is defined by the cordal insertions. Anteroapically, prominent muscle bundles traverse the chamber from septum to free wall and demarcate the trabecular region. It is in this region that biopsy tissue is obtained and transvenous pacemaker leads are lodged. The remainder of the ventricle is relatively smooth walled and forms the outlet region, which is a collar of myocardium known as the conus (meaning cone), infundibulum (meaning funnel), or right ventricular outflow tract.

Within the right ventricle, a nearly circular ring of muscle known as the crista supraventricularis forms an unobstructed opening into the outlet region. It consists of a parietal band, an

Figure 1.10. Ventricular septum, shown schematically. For each ventricle, the septum is roughly triangular-shaped. One side forms the anterior border, and one forms the inferior border. The third side is located at the cardiac base and is associated with AV and semilunar valves. (See text for further description.)

outlet septum, a septal band, and a moderator band (Fig. 1.9). The parietal band is a free-wall structure that separates the tricuspid and pulmonary valves. Lying beneath the right-left commissure of both semilunar valves, the outlet septum separates the two ventricular outflow tracts and tilts approximately 45 degrees relative to the remainder of the ventricular septum. The septal band is a Y-shaped structure with a long, broad stem and smaller inferior and anterior limbs. The two limbs, in turn, cradle the outlet septum and give rise to the medial tricuspid papillary muscle. Apically, the septal band merges with the apical trabeculations and gives rise to the moderator band, which inserts at the base of the anterior tricuspid papillary muscle. The right bundle branch travels along the septal and moderator bands.

When viewed from a right anterior oblique perspective, the ventricular septum is shaped like a triangle, the vertexes of which correspond to the apex, pulmonary annulus, and the most inferior aspect of the tricuspid annulus. Normally, the distance from the apex to the pulmonary valve annulus is about 25% greater than that from the apex to the tricuspid annulus. The membranous septum lies midway between the pulmonary valve annulus and the inferior aspect of the tricuspid annulus.

Using these landmarks, the surface of the ventricular septum can be divided into six regions that are useful for localizing the position of septal defects (Fig. 1.10) (18). A line drawn from the membranous septum to the apex divides the septum into anterior and inferior halves. By dividing the base–apex length into thirds (basal, middle, and apical), the six regions are obtained. The basal and middle regions inferiorly correspond to the inlet portion of the right ventricle, and the two apical regions plus the anterior middle region match the anterobasal trabecular area. The remaining anterobasal region corresponds to the outlet septum.

Left Ventricle

The left ventricle is a left posterior chamber that forms the left border of the radiographic frontal cardiac silhouette (Fig. 1.6). It consists of septal and free-wall components, and its entrance and exit are guarded by the mitral and aortic valves, respectively. The left ventricle is circular in short-axis cross section and is somewhat wedge shaped in the long-axis view. Three-dimensionally, it is shaped like a strawberry and is approximated mathematically as a truncated ellipsoid (Fig. 1.11). It is

Figure 1.11. Three-dimensional shape of the left ventricle. The left ventricle in humans is shaped like a strawberry, here shown whole and in long-axis. Rather than being facetious, this analogy serves to emphasize the complex shape of the chamber. Thus, mathematical formulas used for the determination of chamber volume or myocardial mass are accurate only insofar as they also accurately reflect the actual shape of the left ventricle. In disease states that are commonly attended by appreciable alterations in ventricular shape, the use of standard formulas may result in determinations that are considerably inaccurate.

of interest that, whereas a conical chamber (as in aortic stenosis) uses the least energy for systolic contraction and a spherical chamber (remodeling in dilated cardiomyopathy) requires the least expenditure of energy for diastolic filling, the normal elliptical left ventricular chamber expends the least total systolic and diastolic energy (19).

In the left ventricle, muscle bundles follow a spiral course from apex to base and also form several different layers that crisscross one another. As a result of this arrangement, systole is characterized by twisting or wrenching contractions that effectively wring blood out of the left ventricle, and diastole creates a vortex that literally sucks blood into the left ventricular chamber.

The free wall is thickest basally and then gradually tapers toward the apex. Interestingly, the tip of the apex, called the apical thin point, averages only 1 to 2 mm in thickness, even in hypertrophied hearts. In contrast, the muscular septum forms a rounded peak at its basal summit and becomes thickest at its midportion owing to the contribution of the right ventricular septal band. Then, after thinning a bit, the septum remains relatively constant in thickness and tapers only as it fuses with the apical portion of the free wall.

Direct fibrous continuity exists between the anterior mitral leaflet and the left and posterior aortic cusps, and this region is reinforced bilaterally by the right and left fibrous trigones (see “Base of the Heart” section later in this chapter). In some hearts, small bundles of myocytes are embedded in this fibrous tissue and afford a minor degree of muscular separation between the two valves. With persistence of the left parietal band (so-called double conus), this muscle bundle causes appreciable valvular separation as is often seen in a double-outlet right ventricle.

As in the right ventricle, the septal surface of the left ventricle is roughly triangular. However, in contrast, the distances from the apex to the mitral annulus and from the apex to the aortic annulus are similar. The inflow length is appreciably shorter than the outflow length only with AV septal defects. The membranous septum and the site of mitral–aortic valvular continuity lie at a level midway between the aortic valve annulus and the most inferior portion of the mitral annulus. Thus, in long-axis scans, a line drawn from the point of valvular continuity to the apex will divide the ventricle into an inferior inflow region and an anterosuperior outflow region and allow identification of the site of the membranous septum.

The ventricular apex is characterized by small, shallow trabeculations, and the apical one-half to two-thirds of the septal surface is also finely trabeculated. More basally, the septum is smooth walled, and subendocardially, the left bundle branch travels in this region. The membranous septum lies beneath the right posterior aortic commissure (Fig. 1.9). Because the septal tricuspid leaflet inserts along its midportion, the membranous septum consists of AV and interventricular components, and their relative sizes vary inversely, depending on the level of tricuspid insertion. Moreover, the entire membranous septum varies considerably in size among individuals and tends to be largest in patients with Down syndrome. Septal defects in this region generally are associated with focal elevation of the tricuspid annulus to the level of the mitral valve so that the communication is interventricular rather than atrioventricular.

The outflow tract of the left ventricle is formed by the upper septum, the anterobasal free wall, and the anterior mitral leaflet. Abnormalities in any of these structures may be associated with outflow tract obstruction. Examples include the discrete and tunnel forms of subaortic stenosis and hypertrophic cardiomyopathy. It is found along the anterior free wall, at the entrance to the outflow tract. The anterolateral muscle of the left ventricle is a prominent trabeculation that may cause outflow tract obstruction in association with certain anomalies (20,21). By cardiac imaging, such prominent trabeculations may be misinterpreted as mural thrombus.

Conditions such as aortic stenosis that impose a pressure overload on the left ventricle induce concentric hypertrophy without appreciable dilation (pressure hypertrophy). In contrast, disorders that produce a volume overload, such as chronic aortic regurgitation, are attended not only by concentric hypertrophy but also by chamber dilation (volume hypertrophy). Although pressure and volume hypertrophy each increase the ventricular mass, only pressure hypertrophy is consistently associated with an increased wall thickness. In volume hypertrophy, dilation masks the degree of hypertrophy, and wall thicknesses often are normal although muscle mass is increased (Fig. 1.12). Consequently, when the left ventricle is dilated, wall thickness cannot be used as a reliable indicator of hypertrophy.

As a general rule, only in myocarditis or hyperacute allograft rejection does the left ventricle become dilated without coexistent hypertrophy, owing to the acute nature of the disorder. It also is important to recognize that hypertrophy, with or without dilation, decreases myocardial compliance and may hinder diastolic filling. Many forms of congenital heart disease are associated with moderate to marked degrees

of ventricular hypertrophy, and, as a result, there may be difficulty in achieving adequate myocardial preservation during long operations. Moreover, marked hypertrophy does not always regress significantly following reparative procedures and may become a source for ischemic injury as the patient survives into adulthood.

Comparison of Ventricles

Because the AV valves travel with their corresponding ventricles, the identification of these valves (by noting their different annular insertion levels along the septum) provides an indirect but reliable clinical means of establishing ventricular morphology. The presence of continuity or discontinuity between the AV and semilunar valves is also useful and can be evaluated using various scanning techniques (Table 1.1). Coarse apical trabeculations, indicative of a right ventricle, are identified more readily by angiography than by echocardiography. Although differences in wall thickness and ventricular shapes are characteristic in normal hearts, they often do not apply in malformed hearts.

SEMILUNAR VALVES

General Features

The semilunar valves connect the ventricles to the great arteries and serve to maintain unidirectional blood flow. They consist of an annulus, cusps, and commissures. Because they have no tensor apparatus (tendinous cords and papillary muscles), the semilunar valves are simpler than the AV valves, and their opening and closure are primarily passive processes.

Behind each cusp is an outpouching of the great artery that imparts a tribulbous, or cloverleaf, shape to the arterial root. The junction between the sinus portion of a great artery and its distal tubular portion forms a prominent ridge, the sinotubular junction. From the right and left aortic sinuses, proximal to this junction, arise the right and left coronary arteries, respectively. These often are incorrectly called the right and left coronary sinuses; the coronary sinus, of course, is a venous structure that empties into the right atrium.

The annulus of each semilunar valve assumes the shape of a triradiate crown, the three points of which attain the level of the sinotubular junction and demarcate the commissures. A commissure, in turn, represents the site at which two

Figure 1.12. Geometry of left ventricular hypertrophy and dilation in short-axis views. **A:** As shown schematically, compared with the normal state, pressure hypertrophy produces an increase in both wall thickness and surface area, whereas volume hypertrophy (with chamber dilation) increases the surface area but not the wall thickness. **B:** Compared with a normal heart (center), the heart with pressure hypertrophy (left) has a thick left ventricular wall, but the one with volume hypertrophy (right) has a normal wall thickness.

Figure 1.13. Semilunar valves. **A:** Each cusp is pocket shaped and has a free edge, a closing edge, a nodule of Arantius, and two contact regions (lunulae). The annulus (*dotted line*) for each cusp is U shaped. **B and C:** The aortic valve, viewed from above, is shown in simulated opened (**B**) and closed (**C**) positions. **D and E:** Tomographic sections at the level of the aortic valve show adjacent structures as viewed from above (**D**) and below (**E**). (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

cusps meet along the annulus. Because the valvular orifice approximates the level of the sinotubular junction, autopsy measurements of the arterial diameter and circumference at this level correlate well with clinical measurements of orifice size (1). During the first two decades of life, normal valve size correlates better with age than with parameters of body size.

As half-moon-shaped (semilunar) structures, the cusps represent pocket-like flaps of delicate fibrous tissue. The leading edge of each cusp is its free edge, beneath which lies a shallow biscalloped ridge, the closing edge, along the ventricular surface of the cusp (Fig. 1.13). At the center of each cusp, along the free edge, is a small fibrous mound, the nodule of Arantius. To either side of this nodule, between the free and closing edges, are two crescent-shaped areas called lunulae that represent the contact surfaces between adjacent cusps during valve closure. The arterial surface of each cusp, in conjunction with its arterial sinus, forms the valve pocket.

Like the AV valves, the semilunar valves histologically consist of fibrous (fibrosa) and spongy (spongiosa) layers. Cusps contain little elastic tissue and therefore have little elastic recoil. As passively mobile structures, they have no memory of

shape and no tendency to assume either an opened or a closed position. During isovolumetric ventricular contraction, expansion of the arterial root may produce commissural separation and thereby initiate valvular opening. Each cusp moves in undulating fashion toward its arterial sinus during ventricular systole and then back toward the center of the arterial lumen during ventricular diastole as retrograde blood flow fills each valve pocket.

Pulmonary Valve

The pulmonary valve lies closest to the chest wall, near the upper left sternal border, and its orifice is directed toward the left shoulder. Because the right ventricular myocardium extends onto the pulmonary sinuses, the valve appears partially submerged within a crater of infundibular muscle. The anterosuperior limb of the septal band extends onto the left pulmonary sinus, and trabeculations parallel to the parietal band insert onto the right pulmonary sinus. Trabecular extensions onto the anterior sinus are less prominent. In the setting

of pulmonary atresia with an intact ventricular septum, failure to recognize these features has resulted in burrowing into the pericardial sac rather than into the pulmonary artery during closed operations (Brock procedure). Although the Brock procedure is no longer performed, it is important to remember this potential complication during cardiac catheter manipulations.

Aortic Valve

The annulus of the aortic valve is a midline structure, and its orifice is directed toward the right shoulder. Consequently, its systolic murmurs are best heard along the upper right sternal border and radiate toward the neck. Although the valve cusps are similar in size, in only about 10% of hearts are they truly equal in size. Thus, a minor degree of inequality is the rule, and in two-thirds of hearts, either the right or the posterior cusp is larger than the other two.

By virtue of its central position, the aortic valve and its sinuses contact all four cardiac chambers, an important consideration in evaluating aortic sinus aneurysms of congenital or infectious origin. The right aortic sinus abuts the basal ventricular septum and right ventricular parietal band and is covered in part by the right atrial appendage. In contrast, the left aortic sinus rests against the anterior left ventricular free wall and a portion of the anterior mitral leaflet, abuts the left atrial free wall, and is covered in part by the main pulmonary artery and left atrial appendage. Finally, the posterior aortic sinus overlies the basal ventricular septum and a part of the anterior mitral leaflet, forms part of the transverse sinus, abuts the atrial septum, and indents both atrial free walls as the torus aorticus (aortic bulge).

Comparison of Semilunar Valves

The semilunar valves are named according to the great artery into which they empty, not the ventricle from which they arise. During fetal development and infancy, the aortic and pulmonary valves are virtually identical. However, during childhood, the aortic cusps begin to thicken and become more opaque than the pulmonary cusps as a result of higher left-sided pressures, and this process continues throughout life. The annular dimensions of the aortic and pulmonary valves are similar

from birth through the first four decades of life, but beyond the age of 40 years, the rate of age-related annular dilation is greater for the aortic valve than for the pulmonary valve.

Base of the Heart

The cardiac base is defined by the plane of the AV groove (sulcus) and houses the four cardiac valves (Fig. 1.14). It also contains the fibrous cardiac skeleton, whose purpose is to weld together the valvular annuli, to fuse together but also electrically separate the atria and the ventricles, and to provide a firm foundation against which the ventricles can contract. The cardiac skeleton contains not only the four major valve annuli but also their intervalvular fibrous attachments (the right, left, and intervalvular fibrous trigones and the conus ligament).

The centrally located aortic valve forms the cornerstone of the cardiac skeleton, and its fibrous extensions anchor and support the other three valves. The intervalvular fibrous trigone is interposed between the left-posterior aortic commissure and the anterior mitral leaflet, and the left and right fibrous trigones project from each side and attach to the remainder of the anterior mitral leaflet. Thus, the left, intervalvular, and right fibrous trigones provide the anatomic substrate for direct mitral-aortic valvular continuity.

The membranous septum, in conjunction with the right fibrous trigone, fuses the right posterior aortic commissure to the anteroseptal tricuspid commissure. Therefore, the right fibrous trigone (also known as the central fibrous body) welds together the aortic, mitral, and tricuspid valves and forms the largest and strongest component of the cardiac skeleton. Even in the setting of a membranous ventricular septal defect, this connection is maintained, so that the region of mitral-tricuspid continuity forms the posterior wall of the defect. Near the right-left aortic commissure is a diminutive connection between the aortic and pulmonary valves, the conus ligament (or ligament of Krehl). Thus, each aortic valve commissure is fused to one of the other three valves: left-posterior commissure to mitral valve, right-posterior commissure to tricuspid valve, and right-left commissure to pulmonary valve.

Although schematic drawings of the cardiac base generally show the four valves in the same plane, they actually do not lie in the same plane or even in parallel planes. Because of the intertwining of the great arteries, the aortic and pulmonary

Figure 1.14. Base of the heart. A: The aortic valve is located centrally and abuts the other three cardiac valves. B: The cardiac skeleton, shown schematically, consists of four valvular annuli, three fibrous trigones, a membranous septum, and the tendon of Todaro. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

valves are skewed 60 to 90 degrees as the valvular orifices are directed toward opposite shoulders. Moreover, the tricuspid and mitral valves are skewed 10 to 15 degrees, such that their annuluses approach one another at the membranous septum and diverge along the inferior wall as the coronary sinus is interposed between them. These angles may vary somewhat during the course of the cardiac cycle.

GREAT ARTERIES

General Features

The great arteries include the aorta, pulmonary arteries, and ductus arteriosus. Although the aorta and pulmonary artery represent elastic vessels, the ductus arteriosus has a unique microscopic appearance that changes during fetal and neonatal life.

In the fetus and neonate, the aorta and pulmonary arteries are similar in thickness and in the number of elastic laminae within their medial layers. During the first several months of life, and consequent to the postnatal decrease in pulmonary artery pressure and resistance, the mediastinal pulmonary arteries attenuate and decrease in thickness, and their elastic fibers become irregular and fragmented. Beyond the first year of life, the thickness of the main pulmonary artery is normally less than half that of the adjacent ascending aorta, although the diameters of the two great arteries remain similar.

Interestingly, for patients with persistent pulmonary artery hypertension after birth (as with large unoperated ventricular septal defects), the medial thickness and elastic pattern in the pulmonary arteries remain similar to those in the aorta. In contrast, in patients who develop primary pulmonary hypertension later in life, their pulmonary arteries become thickened and the medial elastic layers retain the appearance of a pulmonary artery rather than that of an aorta.

Pulmonary Arteries

The main pulmonary artery emanates from the right ventricle and travels to the left of the ascending aorta in the general direction of the left shoulder. As it bifurcates, the left pulmonary

artery continues as a smooth arch and courses over the left bronchus, whereas the right pulmonary artery arises at a right angle and travels beneath the aortic arch and behind the superior vena cava. Creation of a Glenn anastomosis between the superior vena cava and right pulmonary artery takes advantage of the close proximity of these two vessels. The main and left pulmonary arteries contribute to the upper left border of the radiographic frontal cardiac silhouette (Fig. 1.6). Because the pulmonary arteries do not exhibit bilateral mirror-image symmetry, the spatial relationship of the main and lobar arteries to their adjacent bronchi differs between the right and left lungs and can be used to determine pulmonary morphology and sidedness (Fig. 1.15; also see Figs. 2.5 and 2.6).

During childhood, the tracheobronchial cartilage is pliable and may be compressed by hypertensive pulmonary arteries. Chronic compression of the left main and right middle lobe bronchi may contribute to the development of recurrent bronchopneumonia or atelectasis in the corresponding lobes. Furthermore, rightward displacement of the aortic arch by a dilated and hypertensive pulmonary trunk can produce tracheal indentation, which may be detected radiographically, and hoarseness owing to compression of the left recurrent laryngeal nerve.

The pulmonary circulation often is referred to as the central or lesser circulation. Within the human lung, pulmonary arteries travel with their corresponding airways and pulmonary veins course within the interlobular septa (*not* septae) (22). Because the pulmonary circulation represents a low-pressure and low-resistance system, its arteries and veins are normally thin walled. In general, pulmonary arteries >1 mm in diameter are elastic vessels, and those <1 mm represent muscular resistance arteries. Because pulmonary arterioles normally contain little medial muscle, the term arteriolar resistance is inaccurate.

During fetal life, a state of physiologic pulmonary hypertension exists owing to patency of the ductus arteriosus and equalization of aortic and pulmonary arterial pressures. As a result, the medial thickness of muscular pulmonary arteries resembles that of systemic arteries. After birth, as the ductus arteriosus closes and pulmonary arterial pressure decreases, attenuation of medial smooth muscle occurs, such that the ratio of medial thickness to external diameter decreases from 20% to 25% in fetuses to <10% in infants 3 to 6 months of age (Fig. 1.16).

Figure 1.15. Pulmonary and bronchial arteries, shown schematically. A: The right and left pulmonary arteries are not mirror-image structures, and neither are the right and left bronchial trees. B: Bronchial arteries usually arise from the descending thoracic aorta at the level of the carina, but they vary in number. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 1.16. Microscopic appearance of the pulmonary circulation. A–C: The medial thickness of muscular pulmonary arteries changes after birth, as shown at birth (A), in a 5-month-old (B), and in a 7-month-old (C). D and E: Pulmonary arteries (D) travel with their airways, and pulmonary veins (E) travel within the interlobular septa. (Elastic van Gieson stain; A–C, high power; D and E, medium power.)

The pulmonary arteries serve to transport systemic venous blood to the lungs for oxygenation and for the release of carbon dioxide. In contrast, nutrition of the bronchial and pulmonary vascular walls is provided by bronchial arteries that arise from the descending thoracic aorta (Fig. 1.15).

Aorta

The aorta is the major elastic artery of the systemic circulation. It arises at the level of the aortic valve annulus and terminates at its bifurcation into the common iliac arteries, at the level of the umbilicus and the fourth lumbar vertebra. The aorta may be divided into four regions: ascending aorta, aortic arch, descending thoracic aorta, and abdominal aorta (Fig. 1.17). Of note, the ascending aorta and aortic arch are derived embryologically from the neural crest, while the descending thoracic aorta and abdominal aorta are derived from the primitive vascular mesenchyme. This fact may help to explain the different pathologic conditions observed in the different aortic regions.

The ascending aorta lies to the right of the main pulmonary artery and is located almost entirely within the pericardial sac. It consists of sinus and tubular portions, which are demarcated by the sinotubular junction, the site at which the discrete form of supravalvular aortic stenosis occurs. The right and left coronary arteries, as the only major branches from the ascending aorta, arise from the right and left aortic sinuses, respectively. During childhood and adolescence, the dimensions of the ascending aorta are related to age and body size.

The aortic arch normally travels over the left bronchus, defining a left aortic arch, and over the right pulmonary artery.

Figure 1.17. Systemic arteries, shown schematically. The aorta consists of ascending, arch, descending thoracic, and abdominal regions. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

From the top of the arch, the brachiocephalic (or innominate), left common carotid, and left subclavian arteries arise, in that order. In about 10% of individuals, the left common carotid artery originates from the brachiocephalic artery, and in 5%, the left vertebral artery arises from the aorta, between the left common carotid and left subclavian arteries. The aortic arch contributes to the left superior border of the radiographic frontal cardiac silhouette and forms the aortic knob.

When the aorta courses over the right bronchus, a right aortic arch exists, and the arch vessels show mirror-image branching. Aberrant retroesophageal subclavian arteries arise from the side of the arch rather than from its top. Most aortic coarctations occur opposite the ductus arteriosus, just distal to the left subclavian artery.

The descending thoracic aorta lies adjacent to the left atrium, esophagus, and vertebral column. Its posterolateral branches are the paired intercostal arteries, and its anterior branches include the bronchial, esophageal, mediastinal, pericardial, and superior phrenic arteries. The bronchial arteries also may arise from the intercostal or subclavian arteries or, rarely, from a coronary artery. Bronchial veins drain not only into the azygos and hemiazygos veins but also into the pulmonary veins (23).

The abdominal aorta lies to the left of midline, adjacent to the vertebral column. Its major lateral branches are retroperitoneal and include the renal, adrenal, lumbar, and inferior phrenic arteries. Although the gonadal arteries originate more anteriorly, they too are retroperitoneal. In contrast, all other branches that arise anteriorly represent intraperitoneal arteries that supply the digestive system, including the celiac artery (with its left gastric, splenic, and hepatic branches) and the superior and inferior mesenteric arteries. Distally, the aorta bifurcates into the common iliac arteries and also gives rise to the middle sacral artery.

Ductus Arteriosus

During fetal life, the ductus arteriosus provides an avenue for communication between the pulmonary and systemic circulations. It is interposed between the proximal portion of the left pulmonary artery and the undersurface of the aortic arch; during intrauterine life, its diameter is similar to that of the descending thoracic aorta and is larger than that of the right or left pulmonary artery. Most of the right ventricular output bypasses the lungs and enters the aorta via the ductus arteriosus. However, soon after birth and with expansion of the lungs, the ductus functionally closes, pulmonary vasodilation occurs, and the entire right cardiac output passes through the lungs (see Chapters 27 and 31).

Throughout gestation, structural changes take place that prepare the ductus arteriosus for rapid functional closure soon after birth (24). Initially, this vessel has the appearance of a muscular artery, in contrast to the elastic arteries to which it connects. During the third trimester, proliferative fibroelastic intimal cushions become prominent and medial thickening results from smooth muscle proliferation and the deposition of collagen, elastin, and glycoproteins. Ultrastructurally, medial smooth muscle cells change from the secretory to the contractile type. Blurring of intimal-medial junctions, coupled with haphazard arrangement of muscle bundles, produces an appearance similar to that of fibromuscular dysplasia. Adventitial elastic fibers become prominent, particularly at each end of the artery.

Constriction of the ductus arteriosus occurs within 24 to 48 hours of birth in term neonates and is mediated by a combination of rising systemic oxygen tension and decreasing circulating prostaglandin E₂ (PGE₂) and prostacyclin (PGI₂) levels. Ductal vasoconstriction, over the next several weeks,

is accompanied by focal medial necrosis, medial edema, disruption of the internal elastic lamina, and mural thrombosis. Subsequently, the deposition of elastin within the arterial wall becomes marked, and focal areas of calcification are the rule, resulting in complete and permanent closure of the ductus arteriosus, persisting from then on as the ligamentum arteriosum. Not surprisingly, ductal closure is hampered in both infants born at high altitude where oxygen tension is lower and in those born prematurely. Both genetic factors and prenatal infection may also play a role in patients with ductus arteriosus patency.

In general, closure of the ductus arteriosus begins near the pulmonary artery and progresses toward the aorta. If this process is incomplete, a small ductal diverticulum remains that characteristically emanates from the undersurface of the aortic arch. Rarely, ductal aneurysms, dissections, or ruptures occur and may be associated with underlying connective tissue disease, surgical manipulation, or active/healed arteritis.

CORONARY CIRCULATION

Coronary Arteries

The right and left coronary arteries arise from their corresponding aortic sinuses. Their ostia (ostiums) are circular to elliptical and originate midway between the aortic valve commissures and about two-thirds of the distance between the annulus and the sinotubular junction. The right coronary artery originates nearly perpendicularly from the right aortic sinus. In contrast, the left main coronary artery arises at an acute downward angle and travels parallel to its aortic sinus wall.

The major epicardial arteries include the left main, left anterior descending, circumflex, and right coronary arteries. Branches of the left anterior descending artery are called diagonals, whereas branches of the right and circumflex arteries are called marginals (Fig. 1.18). Septal perforators represent long intramural branches of the anterior and posterior descending arteries that supply the ventricular septum and, hence, are not epicardial branches.

Proximally, the right coronary artery travels between the main pulmonary artery and the right atrium and is covered by the right atrial appendage. Throughout its course within the right AV groove, the right coronary artery is embedded in epicardial adipose tissue. In about 60% of subjects, the first branch is the conus coronary artery, which supplies the right ventricular outflow tract; in the other 40%, this artery arises independently from the right aortic sinus (25). The descending septal artery nourishes the infundibular septum. Marginal branches include several small vessels and a prominent acute marginal artery.

Beyond the acute margin, along the inferior surface of the heart, the length of the right coronary artery varies inversely with that of the circumflex artery. In about 70% of human hearts, the right coronary artery gives rise not only to the posterior descending branch, as the dominant coronary artery, but also to posterolateral branches, thereby nourishing the right ventricular free wall, the inferoseptal wall of the left ventricle, the posteromedial mitral papillary muscle, and the AV nodal artery.

The left main coronary artery lies between the main pulmonary artery and the left atrium and is covered by the left atrial appendage. It bifurcates into left anterior descending and circumflex branches in most individuals but trifurcates in some, with an intermediate artery emanating between the other two vessels. A short (<8 mm) left main artery often is associated with left coronary dominance. The vast majority of left coronary artery blood flow takes place during ventricular diastole.

Figure 1.18. Coronary circulation, shown schematically. **A:** The right and circumflex arteries travel in the AV groove, near the tricuspid and mitral valves, respectively (cardiac base). **B:** The anterior and posterior descending arteries travel in the interventricular groove and demarcate the plane of the ventricular septum (superior and inferior views). **C:** Coronary dominance is determined by the origin of the posterior descending branch. **D:** The anterior cardiac veins empty directly into the right atrium, whereas the other major epicardial veins drain into the coronary sinus. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Traveling within the anterior interventricular groove, the left anterior descending artery wraps around the apex and extends for a variable distance in the posterior interventricular groove. Including its diagonal and septal perforating branches, this vessel supplies the anteroseptal and anterolateral walls, part of the anterolateral mitral papillary muscle, and the entire apex of the left ventricle. Bridges of myocardium cover small lengths of the left anterior descending artery in about 10% of human hearts, but usually do not interfere with diastolic myocardial perfusion (26).

The circumflex coronary artery travels within adipose tissue in the left AV groove. It generally terminates just beyond its obtuse marginal branches and nourishes the lateral wall of the left ventricle and part of the anterolateral mitral papillary muscle. In about 10% of subjects, the circumflex artery also supplies the posterior descending branch, constituting left coronary dominance, and the inferoseptal wall of the left ventricle, posteromedial mitral papillary muscle, and AV nodal artery. About 20% of human hearts exhibit shared coronary dominance, such that both the right and circumflex arteries provide posterior descending branches.

The sinus nodal artery arises from the right coronary artery in about 60% of hearts and from the circumflex artery in 40%, but its artery of origin does not depend on patterns of coronary dominance. In contrast, the AV nodal artery arises from the dominant coronary artery and, therefore, originates from the right coronary artery in 90% of human hearts. The AV (His) bundle receives a dual blood supply from the AV nodal artery and the first septal perforator of the left anterior descending artery. Nourishment for the right and left bundle branches is provided by other septal perforator branches of the anterior and posterior descending arteries.

The right and circumflex coronary arteries travel in the AV groove and thereby define the plane of the cardiac base. Similarly, the anterior and posterior descending coronary arteries course within the interventricular grooves and indicate the plane of the ventricular septum. Consequently, for surgeons and pathologists, the epicardial coronary arteries are reliable external landmarks for determining relative chamber sizes and valve locations.

Coronary Veins

The coronary veins and cardiac lymphatics work in concert to remove excess fluid from the myocardial interstitium and the pericardial sac. The venous circulation of the heart consists of a coronary sinus system, an anterior cardiac venous system, and a thebesian venous system (Fig. 1.18). The great cardiac vein travels beside the left anterior descending and circumflex coronary arteries to merge with the coronary sinus. At this site is a bicuspid venous valve, known as Vieussens valve. The coronary sinus, in turn, receives the left-posterior, middle, and small cardiac veins, as well as several smaller tributaries, before joining the right atrium. Along the anterobasal aspect of the right ventricular free wall, three or four anterior cardiac veins either empty directly into the right atrium or first join a common collecting vein. Finally, numerous small thebesian veins drain directly into a cardiac chamber, particularly the right atrium or right ventricle.

As an aside, the human heart normally has eight valves. There are four major valves (aortic, mitral, tricuspid, and pulmonary). The right atrium contains three valves (of the fossa ovalis, inferior vena cava, and coronary sinus). The eighth is Vieussens valve, the ostial valve of the great cardiac vein.

Figure 1.19. Cardiac conduction, shown schematically. **A:** Right heart. The sinus node and AV node are both right atrial structures, whereas the AV (His) bundle travels through the right fibrous trigone to reach the summit of the ventricular septum. The right bundle branch travels along the septal and moderator bands. **B:** Left heart. The left bundle branch forms a broad sheet of fibers along the septal surface. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Cardiac Lymphatics

Within the ventricular myocardium is an interconnecting network of delicate lymphatic channels that drain toward the epicardial surface. Along the epicardial surface, the right and left lymphatic channels form and accompany their respective coronary arteries in retrograde fashion toward the aortic root. These are joined by lymphatic channels from the conduction system and a few sparse lymphatic vessels from the atria and the valves (27). As the right and left lymphatic channels coalesce, they travel along the ascending aorta to the undersurface of the aortic arch and drain into a pretracheal lymph node. Next, they course between the superior vena cava and the brachiocephalic artery to join a cardiac lymph node before emptying into the right lymphatic duct. Lymphatics from the parietal pericardium drain into either the right lymphatic duct or the thoracic duct.

CARDIAC CONDUCTION SYSTEM

General Features

The cardiac conduction system consists of the sinus node, internodal tracts, and AV conduction tissues (Fig. 1.19). Its function is influenced by sympathetic and parasympathetic innervation, circulating catecholamines, patency of its nutrient blood supply, regional acid-base or electrolyte disturbances, mechanical trauma (such as sutures, synthetic patches, or ablation procedures), and involvement by neoplasm or infection.

The sinus and AV nodes are both right atrial structures with similar microscopic features, conduction velocities, and action potentials (Table 1.2). Similarities also exist in the structure, conduction velocities, and action potentials of the AV (His) bundle, right and left bundle branches, and working cardiac

TABLE 1.2 Comparison of Components of the Cardiac Conduction System

Site	Location	Cell Types	Cell Diameter (mm)	Conduction Velocity (m/s)	Action Potential
Sinus node	Right atrial subepicardium	P cells	5–10	<0.05	
		Transitional cells	5–10		
Internodal tracts	Atrial septum and free walls	Atrial myocytes	10–15	0.3–0.4	
AV node	Right atrial subendocardium	P cells	5–10	0.1	
		Transitional cells	5–10		
		Purkinje cells	30–60		
AV (His) bundle	Tricuspid valve annulus and ventricular septal summit	Purkinje cells	30–60	2–3	
		Ventricular myocytes	10–20		
Bundle branches	Ventricular subendocardium	Purkinje cells	30–60	2–3	
		Ventricular myocytes	10–20		
Ventricular myocardium	Ventricular septum and walls	Ventricular myocytes	10–20	0.3–0.4	

myocytes. All components of the cardiac conduction system are specialized cardiac myocytes, not nerves, whose major function is conduction rather than contraction.

Sinus Node

As the primary pacemaker of the heart, the sinus node represents a right atrial structure that is located subepicardially, along the terminal groove near the superior cavoatrial junction (Fig. 1.20 and Table 1.2). Because it is found at the border between areas derived from the sinus venosus and the embryonic atrium, the pacemaker often is referred to as the sinoatrial node. It is shaped like a flattened ellipse, through which a prominent sinus nodal artery passes. Numerous autonomic nerves approach the sinus node at both its poles.

Microscopically, the node is characterized by a complex interwoven pattern of P cells and transitional cells, within a fibrous stroma, and an outer coat of working atrial myocytes

(28). Because these specialized cells primarily are concerned with conduction rather than contraction, they have fewer contractile elements and expend less energy than working myocytes. Although P cells are thought to be the source of impulse formation, changes in autonomic input may alter the actual pacing site within the node.

Among patients with the asplenia syndrome and right isomerism, bilateral sinus nodes may be encountered. In contrast, in the setting of polysplenia and left isomerism, the sinus node can be congenitally absent or malpositioned. During surgical operations such as the Mustard and Fontan procedures, the sinus node and its artery are susceptible to injury.

Internodal Tracts

Whether specialized conduction pathways exist between the sinus and AV nodes has been the subject of much controversy. Electrophysiologic studies support the concept

Figure 1.20. Location of the cardiac conduction system (indicated in *black ink*). **A:** The sinus node lies subepicardially in the terminal groove of the right atrium (right lateral view). **B:** The AV node represents a subendocardial right atrial structure that lies within the triangle of Koch (*dashed lines*), and the AV (His) bundle travels through the tricuspid annulus to rest along the summit of the ventricular septum. **C:** The right bundle branch is a small cordlike structure that courses along the septal and moderator bands (opened right ventricle). **D:** In contrast, the left bundle branch represents a broad sheet of fibers that travels subendocardially along the left side of the ventricular septum. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

of preferential pathways, but morphologic studies do not. Recent investigations suggest that both views may be correct. The three internodal tracts identified electrophysiologically correspond to those regions of the atrial septum and right atrial free wall, such as the crista terminalis, that contain the greatest concentration of myocytes. Thus, microscopically, these regions consist of working atrial myocytes rather than specialized P, transitional, or Purkinje cells.

Because the septal preferential pathways near the fossa ovalis travel anterosuperiorly in its limbus, internodal conduction disturbances would not be expected following a Rashkind balloon atrial septostomy, in which the valve of the fossa ovalis is torn, or a Blalock–Hanlon posterior atrial septectomy. However, for operations in which the atrial septum is resected, as in the Mustard and Fontan procedures, such disturbances can occur. Similarly, disruption of the crista terminalis may interfere with normal internodal conduction.

Atrioventricular Node

Like the sinus node, the AV node is a right atrial structure that is richly innervated by parasympathetic and sympathetic fibers. In contrast, it is located subendocardially, rather than subepicardially, within the triangle of Koch and adjacent to the right fibrous trigone (or central fibrous body). The triangle of Koch, in turn, corresponds to the AV septum and is bordered by the septal tricuspid annulus, coronary sinus ostium, and tendon of Todaro, a subendocardial fibrous cord that travels from the thebesian–eustachian valvular commissure to the membranous septum (Fig. 1.20). The AV nodal artery, or several of its branches, travel near the node but not necessarily through it, and venous and lymphatic channels are abundant in and around the node.

Microscopically, the AV node consists of a complex interwoven pattern of specialized cardiac muscle cells within a fibrous matrix, similar to the sinus node (28). Proximally, at its junction with the internodal tracts, the AV nodal tissues are loosely arranged and consist primarily of transitional cells and a few working atrial myocytes. Centrally, the node is more compact and is characterized by an interlacing arrangement of P cells. Distally, Purkinje cells begin to form parallel bundles as the node merges with the His bundle. Around its periphery, the AV node contains transitional cells and an outer insulating coat of collagen.

Because of its right atrial location near the tricuspid annulus, the AV node is susceptible to injury during annuloplasty procedures for tricuspid regurgitation and during plication procedures for the Ebstein malformation. In the setting of AV septal defects, involving the expected site of the AV node, the node and His bundle are displaced posteroinferiorly and are associated with relatively specific electrocardiographic alterations. Interestingly, in hearts affected by congenitally corrected transposition of the great arteries, both anterior and posterior AV nodes are observed, usually with a sling of His bundle tissue between the two.

Atrioventricular (His) Bundle

The AV (His) bundle arises from the distal portion of the AV node and travels through the central fibrous body (right fibrous trigone) to reside along the basal ventricular septum, adjacent to the membranous septum. It thereby represents the only normal avenue for electrical conduction between the atrial and ventricular myocardium. Within the central fibrous body, the AV bundle is related closely to the annuli of the aortic, mitral, and tricuspid valves, and its location is somewhat variable along the basal ventricular septum. Thus, during operative procedures involving these valves or a membranous

ventricular septal defect, care must be taken to avoid injury to the His bundle. In some cases of congenital AV block, discontinuity exists between the AV node and the AV bundle.

Microscopically, the AV bundle can be divided into two regions: the penetrating portion, which courses through the central fibrous body, and the branching portion, which gives rise to the right and left bundle branches. Both regions are characterized by numerous parallel bundles of Purkinje cells and working ventricular myocytes, separated by delicate fibrous tissue (28). During fetal and neonatal life, these conduction bundles often are dispersed or separated within the central fibrous body. The final destination of each bundle within the right or left ventricle is probably determined by its position proximally within the penetrating portion of the His bundle. Like an electrical wire, the entire AV bundle is insulated by a dense fibrous sheath.

In many individuals, additional connections exist between the AV conduction system and the atrial and ventricular myocardium. In some, atrial myocardium either joins the distal AV node via the atrionodal bypass tracts of James or connects to the AV bundle through the atriofascicular tracts of Brechenmacher. In others, nodoventricular and fasciculoventricular bypass fibers of Mahaim link the AV node and AV bundle, respectively, to the underlying ventricular septal myocardium. These accessory pathways are apparently nonfunctional in most individuals, although they may produce ventricular preexcitation in some.

However, ventricular preexcitation more often is associated with aberrant bypass tracts that span the annulus of the tricuspid or mitral valve, traveling either through the fibrous ring or within the adipose tissue in the AV groove. Such bypass tracts can be single or multiple and may be identified by electrophysiologic mapping. In contrast, nodules of specialized conduction tissue, representing the bundles of Kent, are located in the right lateral AV groove but usually do not provide a connection between atria and ventricles.

Bundle Branches

The right bundle branch emanates from the distal portion of the AV (His) bundle and forms a cord-like structure that travels along the septal and moderator bands toward the anterior tricuspid papillary muscle. In contrast, the left bundle branch represents a broad fenestrated sheet of subendocardial conduction fibers that spreads along the septal surface of the left ventricle. As it courses toward the ventricular apex and both mitral papillary muscles, the left bundle branch may separate into two or three indistinct fascicles. Left ventricular pseudotendons also may contain conduction tissue from the left bundle branch (29). Microscopically, the bundle branches consist of Purkinje cells and ventricular myocytes (28).

In the setting of a membranous ventricular septal defect, the AV conduction tissues travel along the posteroinferior rim of the defect. However, if AV discordance coexists, the conduction fibers course along the anterosuperior aspect of the defect. For the outlet, inlet, and muscular forms of ventricular septal defect, the AV conduction tissues generally are remote from the defect. Interestingly, following a right ventriculotomy for reconstruction of the right ventricular outflow tract, the electrocardiogram characteristically exhibits a pattern of right bundle branch block, even though the right bundle has not been disrupted.

Cardiac Innervation

Because the embryonic heart tube first forms in the future neck region, its autonomic innervation also originates from this level. From the cervical ganglia arise three pairs of cervical sympathetic cardiac nerves, which intertwine as they join the cardiac plexus between the great arteries and the tracheal bifurcation.

Several thoracic sympathetic cardiac nerves arise from the upper thoracic ganglia and also join the cardiac plexus. From the parasympathetic vagus nerves emanate the superior and inferior cervical vagal cardiac nerves and the thoracic vagal cardiac nerves, which also enter the cardiac plexus. These nerves then descend from the cardiac plexus onto the heart and innervate the coronary arteries, conduction system, and myocardium. In addition, afferent nerves concerned with pain and various reflexes ascend from the heart toward the cardiac plexus.

Transplanted hearts are completely denervated early after transplantation and can respond only to circulating substances, such as catecholamines, but usually not to autonomic impulses. Moreover, because afferent pathways are also lost, coronary obstruction owing to chronic transplant vasculopathy may be associated with undetected myocardial ischemia, because chest pain cannot develop.

EXAMINATION OF CARDIAC SPECIMENS

General Features

Evaluation of cardiopulmonary specimens from patients with congenital heart disease entails more than documentation of the underlying anomalies, although this is certainly important. The recognition of malformations in other organ systems is necessary for the identification of various syndromes, which can have implications for genetic counseling. In addition, the presence of secondary obstructive lesions in the pulmonary vasculature may be more significant in explaining the demise of a patient than the underlying cardiac anomalies. Other processes, such as infections or protein-losing enteropathy, also may be important.

In the 21st century, it is distinctly uncommon for subjects with congenital heart disease to have received no interventional therapy, either in the operating room or in the cardiac catheterization laboratory. Hence, the investigation of cardiopulmonary specimens also entails an evaluation of old and recent procedures, addressing not only their effectiveness but also their secondary effects on the heart and the pulmonary circulation. This includes recognition not only of the complications of therapy but also of the beneficial effects, such as the regression of obstructive pulmonary vascular disease.

Pathologists who evaluate treated forms of congenital heart disease often act in the capacity of a medical archeologist, searching for the telltale results of procedures performed at various times in the past. In complex cases, accurate conclusions can be reached only if accurate and complete historical information is available concerning clinical diagnoses and previous procedures. For example, in patients with multiple interventions, the results of reconstruction and takedown procedures may so alter the underlying morphology that identification of the original anomalies or even previous procedures becomes difficult or impossible.

To relay this information to one's clinical colleagues, a pathologist should not only provide a written report, often with schematic diagrams, but also be prepared to review the actual specimen with others. Such reviews may represent informal sessions, formal conferences, or publications, and therefore can involve the specimen itself or its photographs. In this regard, methods of dissection and photography should be chosen that display the lesions most clearly and accurately. Details of these various methods are discussed below. If one does not have the time, training, or interest to dissect operated hearts with congenital anomalies, referral to a pathologist who does represents a reasonable option.

In the past, for the dissection of congenitally malformed hearts, it was recommended that the heart and lungs be maintained as one intact specimen. Based on personal experience,

however, if the pulmonary arterial and venous connections are normal, then the lungs can be removed from the heart without compromising the accuracy of the evaluation. In fact, both the inspection and photography of the heart generally are easier if the lungs and tracheobronchial tree are removed (but not discarded). In contrast, the entire thoracic aorta with appreciable lengths of its brachiocephalic branches should remain attached to the cardiac specimen.

Inflow–Outflow Method

In the inflow–outflow method, the heart is opened according to the direction of blood flow (30). First, scissors are used to make an incision from the inferior vena cava to the right atrial appendage. The superior vena cava is left unopened so as not to disturb the region of the sinus node. Both the inflow and outflow cuts for the right ventricle are made about 0.5 cm from the ventricular septum, with either scissors or a knife, from the right atrium to the ventricular apex and then from the apex to the pulmonary artery. Contrary to older recommendations, there is no reason to avoid cutting through an abnormal valve when using this method of dissection.

The left atrium is best opened from a point between the right upper and lower pulmonary veins to the tip of the left atrial appendage. In contrast to the right ventricle, the left ventricular inflow tract is opened not along the septum but rather along the lateral wall, between the mitral papillary muscles, from the left atrium to the left ventricular apex. From the apex to the aortic valve, the outflow cut follows the junction with the ventricular septum, generally forming a gentle inverted S-shaped curve. Whereas the inflow cut is best made with a long knife, the outflow cut is best accomplished using a scalpel.

Once the aortic annulus is crossed, scissors can be used to continue cutting through the left aortic cusp. Because of the normal intertwining of the great arteries, further dissection into the ascending aorta requires transection of the main pulmonary artery. The aortic arch is then opened along its left lateral border and, as a continuous dissection, the descending thoracic aorta is opened posteriorly, between the paired intercostal arteries. Once the great arteries are opened, the origins of the coronary arteries and the patency of the ductus arteriosus can be evaluated.

The inflow–outflow method of cardiac dissection is easy to learn and quick to perform. Although it has withstood the test of time and is currently the most popular dissection method among pathologists, it is recommended primarily for normal hearts and perhaps for simple or unoperated forms of congenital heart disease (Fig. 1.21A,B).

Base-of-Heart Method

Removal of the atria and the great arteries just above their corresponding valves allows visualization and inspection of the cardiac base (Fig. 1.14). This method is useful for the evaluation of valvular anomalies or the effects of valvular surgery on nearby structures (Fig. 1.21C). For example, following tricuspid annular plication for an Ebstein anomaly, possible kinking of the right coronary artery may be investigated by this method.

Window Method

In selected cases, hearts prepared by perfusion fixation, paraffin infiltration, or plastination may be examined by cutting windows from the cardiac chambers or great vessels (Fig. 1.21D). In this manner, the interior of the heart or vessels can be viewed without greatly disturbing the internal structures. Although such specimens can be visually stunning, their preparation and photography can be difficult.

Figure 1.21. Nontomographic methods of dissection in malformed hearts. A and B: Inflow–outflow method. In (A), the right ventricle in a specimen with tetralogy of Fallot is opened to display the ventricular septal defect (with an arrow-shaped probe coming from the left ventricle), overriding aorta, and pulmonary stenosis (probe). In (B), an opened left ventricle demonstrates the position of a membranous ventricular septal defect (*). C: Base-of-heart method. The atria and great arteries have been removed to show the cardiac valves in a case of truncus arteriosus. D: Window method. The great arteries have been unroofed to demonstrate a patent ductus arteriosus. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Tomographic Method

In the tomographic method, the heart is bisected (divided into two pieces) by one plane of section. With the bread-slice technique, multiple sections are made parallel to the AV groove, producing numerous ventricular slices. For the past several decades, this popular method has been used by pathologists for the evaluation of ischemic heart disease. It is identical to the short-axis method used in clinical imaging and represents the most common method of cardiac dissection used at our institution for the evaluation of acquired heart disease. It also may be performed concomitantly with the base-of-heart method.

In addition to the short-axis method, the long-axis and four-chamber planes represent other tomographic sections commonly obtained clinically and may be correlated with anatomic features in normal hearts. Other planes, parallel to the standard anatomic directions, also have been used clinically, not only for transesophageal echocardiography but also for magnetic resonance imaging (31). These include frontal (coronal), parasagittal (lateral), and horizontal (transverse) planes of section. In cardiac specimens, any of the aforementioned tomographic planes can be applied not only to normal hearts but also to acquired and congenital forms of heart disease (Figs. 1.22–1.25) (32).

Figure 1.22. Tomographic methods of cardiac dissection (short-axis and frontal views), shown in normal hearts. A–C: Short-axis views, at the levels of the mitral valve orifice (A), left ventricular outflow tract (B), and aortic valve (C). D–F: Frontal (coronal) views, at the levels of the ventricular septum (D), membranous septum (E), and left atrium (F). (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 1.23. Tomographic methods of cardiac dissection (long-axis and two-chamber views), shown in normal hearts. A and B: Long-axis views show inflow and outflow tracts of right ventricle (A) and left ventricle (B). C: Long-axis view of thoracic aorta shows left bronchus and right pulmonary artery traveling beneath aortic arch. D: Two-chamber view demonstrates inflow tract of left ventricle. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Although the tomographic method of cardiac dissection has been used by anatomists and pathologists for more than a century, it has not been accepted widely, probably because it is time-consuming and requires prior fixation (preferably perfusion fixation). Nonetheless, perhaps no other technique allows the assessment of intracardiac relationships as well as the cross-sectional method. For congenitally malformed hearts, tomographic sections are particularly well suited for demonstrating not only the primary anomalies and various interventions but also their secondary effects on the heart. Thus, photographs of specimens dissected tomographically provide clarity as teaching tools and correlate well with current clinical imaging modalities.

Technically, the best cardiac cross sections are generally achieved when a perfusion-fixed specimen is cut in one continuous cut with a very sharp knife. Sawing motions are to be avoided. Moreover, after one section has been made and documented photographically, the specimens can be glued back together and resectioned along another tomographic plane. For this purpose, any of the readily available cyanoacrylate glues (such as Krazy Glue or Super Glue) will suffice. The best results are attained with smooth dry surfaces; roughened sur-

faces (such as those produced by using scissors) may adhere poorly.

Photography of Cardiac Specimens

It is difficult to overestimate the role of photography in the teaching of congenital heart disease. Although schematic diagrams are helpful, the visualization of actual specimens often is necessary for an appreciation of three-dimensional features. In this regard, the well-planned dissection and photography of a classic lesion may be remembered far longer than written words (33). Having access to the most expensive photographic equipment, however, does not guarantee good results. Careful planning and attention to detail are more important.

The use of a high-resolution digital camera has essentially replaced film-based cameras in the field of specimen photography. However, certain basic rules of photography still apply. For example, to increase the depth of field of focus, the aperture should be as small as possible (achieved by setting the f-stop as large as possible, preferably 16 or greater). One of the simplest yet most important factors for attaining high-quality

Figure 1.24. Tomographic methods of cardiac dissection (four-chamber and horizontal views) shown in normal hearts. A–C: Four-chamber views, at levels of coronary sinus (A), fossa ovalis (B), and aortic valve (C). D–F: Horizontal (transverse) views at levels of ventricular inflow (D) and outflow (E) tracts and pulmonary artery (F). (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 1.25. Tomographic methods of dissection in malformed hearts. **A:** Short-axis view of common AV valve in complete AV septal defect. **B:** Short-axis view of right anteriosuperior aorta in complete transposition of the great arteries. **C:** Long-axis view of hypoplastic left ventricle in aortic atresia. **D:** Four-chamber view of right-sided dilation in an Ebstein malformation. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

photographs is the initial focusing of the camera. Few things can ruin a photograph as quickly and irreversibly as failure to attend to sharp focusing.

The use of black or white backgrounds is favored over backlighting through translucent sheets of colored plastic. In this regard, it is important to note that standard black poster board, available from art supply stores, is generally made with water-soluble ink and will stain the specimens.

Because fresh specimens have shiny surfaces that produce extensive glare, tissues should be fixed before being photographed. Maintenance of lifelike colors can be achieved by fixation in formalin for only brief periods (5 to 15 minutes) or in nonformalin fixatives such as Kaiserling or Jores (32). For perfusion-fixed specimens that have been in formalin less than a week, colors may be partially restored by soaking the tissues in 80% ethanol for 15 to 30 minutes. Specimens are then thoroughly dried with paper towels to eliminate reflective glare.

In some cases, pins are necessary to hold thin or collapsible structures in position. From a technical perspective, a piece of black cardboard is placed on a piece of similarly sized corkboard, and the specimen is placed on the cardboard. Pins of

various sizes are then used to stabilize the specimen, and the heads of the pins are removed with cutting pliers so they will not be visible in the photograph (32). For example, 46 pins were used in Figure 1.7E to hold the atrial walls and valve leaflets upright. Probes, arrows, transillumination, and normal specimens (for comparison) also may be used to highlight specific morphologic features.

Classification and Terminology of Cardiovascular Anomalies

William D. Edwards ■ Joseph J. Maleszewski

PERSPECTIVES ON NOMENCLATURE

Through 5,000 years of recorded human history, only during the past 60 have treatments become available to substantially improve the quality of life and increase the longevity of children with cardiac anomalies. Within these 60 years, diagnostic and interventional procedures have been developed that have defined the frontiers of medical technology and creativity. During these exciting and innovative times, however, seeds were also sown, in the form of redundant and overlapping terminology, that have inadvertently led to difficulty and confusion for those interested in the subject of congenital heart disease.

Diversity of Terminology

Drawings and descriptions of malformed hearts date back to the 18th century, and in the mid-19th century, Peacock (1) published 18 cases in his classic series. However, it is the categorization of 1,000 malformed hearts by Dr. Maude E. Abbott at McGill University, published by the American Heart Association in 1936, that stands as a landmark in the classification of congenital heart disease (2). Since that time, others have examined large numbers of cases, both from autopsies and from living patients, and have proposed different systems of classification and nomenclature (3–13). Furthermore, numerous classifications have been adopted for individual anomalies, such as ventricular septal defects, and for groups of anomalies, such as hearts with univentricular atrioventricular connections.

Each new system, however, has reflected not only the state of knowledge at the time of its formulation but also the particular interests or biases of its creators. Thus, among the various classifications, some researchers have emphasized surgical anatomy, some embryogenesis, others spatial relationships such as atrial sidedness and the positions of ventricles and great arteries, and still others clinical features such as cyanosis and altered pulmonary blood flow. Not surprisingly, the introduction of new systems of classification has been attended by changes in terminology, primarily to clarify or simplify certain concepts. But as newer terms have been introduced, older terms have rarely been abandoned. As a result, the nomenclature for congenital heart disease has become a sea of synonyms, adding confusion rather than clarity to an already complex subject (Appendix 2.1, at <http://solution.lww.com>).

Unity from Diversity

Is the development of a unified system of nomenclature a realistic and worthwhile goal? If so, who should decide on the acceptable terminology? And what price will be paid to gain unity at the expense of diversity? Although such a system would limit the confusing number of synonyms that now exist, it also could limit our perspective as certain terms (such as

those with an embryologic basis) are purged from our rich and diverse heritage.

Nevertheless, a movement is already well under way to establish such a unified system. Uniform acceptance, however, will probably be achieved only following the publication of a consensus report from an international group that represents all disciplines dealing with congenital heart disease. To date, such attempts have met with only limited success (14). The system that is eventually chosen should be accurately descriptive, internally consistent, clinically usable, readily codable in a database, and applicable to all forms of congenital heart disease. New terms should be accepted only if they are necessary, brief, and specific (3).

Until such a consensus report is available, it is premature to endorse a specific system of nomenclature. However, at least at an institutional level, those dealing with patients having congenital heart disease should agree to speak the same clinical language and to prescribe to a single system of terminology. For this chapter, the approach and terminology suggested by Anderson et al. (4) are emphasized, with some modifications. Commonly used Latin terms and their anglicized counterparts are provided in Appendix 2.2 at <http://solution.lww.com>.

Although the notation system proposed by Van Praagh (3) is not emphasized in this chapter, it is favored at some institutions and warrants summarization. The situs (sidedness) is determined separately for the atria, ventricles, and great arteries. Atrial situs may be solitus (S), inversus (I), or ambiguous (A). Ventricular situs is solitus or D-loop (D), inversus or L-loop (L), or ambiguous (X). Great arterial situs is designated as solitus (S), inversus (I), D-transposition/malposition (D), L-transposition/malposition (L), or ambiguous or anterior transposition/malposition (A). Abbreviations are listed within the parentheses, with the ventriculoarterial arrangement included before the parentheses and any atrioventricular malalignments or other anomalies stated after the parentheses. Thus, TGA (S,D,D) would correspond to complete transposition of the great arteries.

SEQUENTIAL SEGMENTAL ANALYSIS

For evaluating patients with suspected congenital heart disease, it is helpful to consider the heart as a segmented structure represented by three regions—atria, ventricles, and great arteries (3–6). Each region, in turn, is partitioned into two components, usually right-sided and left-sided. Atrioventricular valves serve as connectors between atria and ventricles, and semilunar valves join the ventricles to the great arteries. There are only a limited number of possible connections between the three major regions, regardless of their spatial orientations. In practice, each region is evaluated independently, following the direction of blood flow: (a) systemic and pulmonary veins, (b) atria, (c) atrioventricular valves, (d) ventricles and

right ventricular outflow tract (infundibulum or conus), (e) semilunar valves, and (f) great arteries.

In a systematic manner, right-sided and left-sided structures at each level are evaluated according to their morphology, their relative positions, their connections to proximal and distal segments, and the presence and location of shunts, obstructions, and valvular regurgitation (7). This constitutes the sequential segmental method for investigation of congenital heart disease, and it represents a diagnostic cornerstone both for clinicians and for pathologists. Before applying this method, however, it is important to determine the cardiac position and the visceral situs (sidedness).

CARDIAC POSITION AND APICAL DIRECTION

With regard to the position of the heart in the chest, two questions arise that can be answered independently: Where is the heart located, and what is the direction of the cardiac apex? Unfortunately, the terms levocardia, dextrocardia, and mesocardia are commonly used to answer both questions, thus imparting an element of ambiguity (3,4). Although the approach described below is not universally accepted, it does provide clarity by defining the cardiac location and apical direction separately and by avoiding the ambiguous Latin terms.

Location in the Chest

Within the thorax, the heart can be described positionally as left-sided (normal), right-sided, or midline. This designation is particularly useful radiographically, before a patient has been evaluated by other imaging techniques.

The position of the heart in the mediastinum is affected not only by underlying cardiac malformations but also by abnormalities in adjacent structures. It can be displaced by conditions that distort the shape of the thorax, such as severe scoliosis or an elevated diaphragm, or that alter the size of thoracic structures, such as a hypoplastic lung or diaphragmatic hernia. Rightward displacement of the heart constitutes dextroposition, a leftward shift represents levoposition, and shifts toward the midline are called mesoposition.

In rare instances, sternal or diaphragmatic defects exist and are associated with an extrathoracic heart, or ectopia cordis (ectopic heart). This condition may be partial or complete and can be further categorized as cervical, thoracocervical, thoracic, thoracoabdominal, or abdominal.

Orientation in the Chest

The direction in which the ventricles are aligned defines the base–apex axis of the heart and may be leftward, rightward, or midline (Figs. 2.1 and 2.2). Leftward ventricles represent

Figure 2.1. Cardiac base–apex axis.

A: The three types are shown schematically and are independent of cardiac position or situs. B: The ventricular apex is leftward (arrow), even though a hypoplastic right lung has caused dextroposition of the entire heart. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 2.2. Cardiac base–apex axis (arrows) shown in three specimens, viewed anteriorly. **A:** Normal heart, with a leftward apex. **B and C:** Congenitally corrected transposition of the great arteries, showing a box-shaped midline apex (**B**) and a rightward apex (**C**).

the normal state and are characterized by an apex that is directed leftward, anteriorly, and somewhat inferiorly. The extent of these three directions is variable and is influenced by age, body build, and the level and functional state of the diaphragm. Ventricles with a rightward apex are directed to the right of midline. In contrast, midline ventricles are often box shaped and exhibit two apices that are directed anteriorly and inferiorly (7).

The base–apex axis is independent of cardiac location and displacements. For example, a patient with a hypoplastic right lung could have a right-sided heart, owing to dextroposition, and still exhibit a leftward apex (Fig. 2.1B).

The base–apex axis is also independent of cardiac sidedness. Thus, the presence of a leftward apex does not necessarily imply normal sidedness (*situs solitus*), and a right-sided apex does not always coincide with mirror-image sidedness (*situs inversus*). A midline apex, on the other hand, usually is associated with cardiac isomerism (*situs ambiguus*).

VISCERAL SIDEDNESS (SITUS)

All major organ systems begin their embryologic development as midline structures with bilateral mirror-image symmetry. However, three organ systems (cardiovascular, respiratory, and digestive) later acquire asymmetry and are thereby characterized by sidedness (*situs* or handedness), which is genetically determined. Sidedness may be normal, mirror-image, isomeric, or indeterminate. Right isomerism indicates bilateral right-sidedness, whereas left isomerism denotes bilateral left-sidedness.

Isomerism and Splenic Anomalies

The relationship between isomerism and splenic anomalies is intriguing (8). The splenic anlage, rather than originating as a midline structure, appears to be left-sided from its inception. Thus, when right isomerism exists, the spleen is usually absent (asplenia syndrome). Left isomerism, in contrast, is generally

associated with multiple spleens (polysplenia syndrome) that are confined to only one side of the vertebral column. Occasionally, subjects with asplenia or polysplenia have normal hearts, and, rarely, those with atrial isomerism have normal spleens.

Abnormalities may affect the entire body, as in total mirror-image sidedness (*situs inversus totalis*), or can involve individual organ systems. Moreover, sidedness may vary between systems, particularly in conditions associated with isomerism. Although the term *atriovisceral situs* enjoys common usage, it does not always allow an accurate description of sidedness in right isomerism and left isomerism. Consequently, it is recommended that the sidedness of cardiovascular, respiratory, and digestive systems be designated separately (7).

Cardiac Sidedness (Situs)

Cardiac sidedness is determined by the position of the morphologic right atrium (Fig. 2.3). It is not determined by the direction of the cardiac apex, the positions of the ventricles or great arteries, or the sidedness of noncardiac viscera. The morphologic right atrium is normally right-sided but is left-sided in *situs inversus* (mirror-image sidedness). Bilateral right atria define right cardiac isomerism, and bilateral left atria constitute left cardiac isomerism (Fig. 2.4) (14). In some cases of polysplenia, one chamber represents a left atrium, but the other has a hybrid appearance that is morphologically neither left nor right; this constitutes indeterminate cardiac sidedness. In practice, an accurate determination of cardiac sidedness depends on an accurate distinction between right and left atrial morphology, as discussed in this chapter and in Chapter 1. Although all investigators agree on the concept of normal and mirror-image cardiac sidedness, some have questioned the existence of atrial isomerism (9).

Pulmonary Sidedness (Situs)

Pulmonary sidedness is determined by the positions of the morphologic right and left lungs (Fig. 2.5). Pulmonary morphology,

Figure 2.3. Cardiac situs (sidedness), shown schematically. A: Situs solitus, with right-sided morphologic right atrium. B: Situs inversus, with left-sided morphologic right atrium. C and D: Situs ambiguus, with bilateral morphologic right atria (right isomerism) (C) and bilateral morphologic left atria (left isomerism) (D). (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 2.4. Cardiac situs in two specimens, displayed in the four-chamber format. A: Situs solitus. B: Situs ambiguus, with right isomerism. A crista terminalis is present bilaterally. Ventricular inversion is also present but plays no role in determining cardiac sidedness. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 2.5. Pulmonary situs, shown schematically. A: Situs solitus, with right pulmonary anterior to its upper lobe bronchus and with left pulmonary artery posterior to its upper lobe bronchus. B: Situs inversus, with mirror-image morphology. C and D: Situs ambiguus, with bilateral morphologic right lungs (right isomerism) (C) and bilateral morphologic left lungs (left isomerism) (D). (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

in turn, is defined by the relationship of the pulmonary arteries to their adjacent bronchi, and not by the number of lobes. The pulmonary artery of a morphologic right lung travels anterior to its upper and intermediate bronchi, whereas that of a morphologic left lung travels superior to its main bronchus and posterior to the upper lobe bronchus.

Clinically, pulmonary sidedness may be inferred by comparing the relative lengths of the two main bronchi, as measured on a chest radiograph that shows an air bronchogram. Normally, the distance from the carina to the origin of the upper lobe bronchus is 1.5 to 2.5 times greater for the morphologic left lung than for the right lung, and this ratio holds true regardless of the sidedness of the aortic arch (which is determined by the bronchus over which the aorta travels) (10). With pulmonary isomerism, this ratio approaches unity because the lengths of the two mirror-image bronchi are similar (Fig. 2.6).

Although most examples of bilateral trilobed lungs do correspond to cases of right isomerism or asplenia syndrome, bilateral bilobed lungs more often occur as a variation of normal morphology than as a manifestation of left isomerism or polysplenia.

Abdominal Sidedness (Situs)

Abdominal sidedness is determined by the location of the liver and stomach, with the spleen and pancreas generally on the same side of the vertebral column as the stomach (Fig. 2.7). The state of the spleen can be evaluated by clinical imaging, thus supplanting the less reliable method of identifying Howell-Jolly bodies in peripheral blood smears. At autopsy, splenic morphology should always be designated in patients with congenital heart disease.

In the asplenia syndrome, the liver is commonly midline with two mirror-image right lobes (right hepatic isomerism), and the biliary tree is patent and is usually associated with a single gallbladder (Fig. 2.8). The position of the stomach and pancreas can be left-sided, right-sided, or midline. Malrotation of the bowel is the rule, such that the cecum and appendix may be located in any of the abdominal quadrants. Finally, the aorta and inferior vena cava travel together on the same side of the vertebral column, a unique feature that can be demonstrated by abdominal imaging.

Interestingly, with the polysplenia syndrome, the sidedness of the abdominal viscera may be indeterminate (ambiguous), mirror-image (inversus), or even normal (solitus). Although the spleens are multiple, they are all located on the same side of the vertebral column as the stomach. The gallbladder is single, but biliary atresia may occur. As a rule, the inferior vena cava fails to join the heart directly and exhibits azygos continuation, with connection to the superior vena cava.

MORPHOLOGY OF CARDIAC SEGMENTS

Accurate identification of right-sided and left-sided structures is an essential feature of the sequential segmental approach to the diagnosis of congenital heart disease. For consistency and reproducibility of diagnoses, definitions of even the most commonly used terms are helpful.

In this regard, a distinction between the terms connection and drainage is necessary because the two are not synonymous. *Connection* is an anatomic term that implies a direct link between two structures. In contrast, *drainage* is a hemodynamic term that refers to the direction of blood flow.

Figure 2.6. Pulmonary situs in four specimens, viewed posteriorly. A: Normal situs, with long left bronchus and short right bronchus. B: Normal situs, with tracheal origin of the right upper lobe bronchus (bronchus suis) (*arrow*). C: Right pulmonary isomerism, with short bronchi of similar length (the posterior wall of the airways has been removed). D: Left pulmonary isomerism, with long bronchi of similar length. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 2.7. Abdominal situs, drawn schematically. A: Situs solitus, with right-sided liver, left-sided spleen (also stomach and pancreas, not shown), and cecum in right lower quadrant. B: Situs inversus, with mirror-image morphology. C: Situs ambiguus with right isomerism shows liver with two right lobes, malrotation of the bowel (indicated by the abnormal position of the cecum), and asplenia. D: Situs ambiguus with left isomerism shows polysplenia; other features are variable. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 2.8. Abdominal situs in two patients, with thoracoabdominal organs viewed anteriorly. **A** and **B**: Both patients had the asplenia syndrome, with right isomerism of the heart, lungs, and abdominal organs. Both exhibit a midline symmetric liver and malrotation of the bowel (with the small bowel to the right and the large bowel to the left). (As an aside, cardiac situs is not affected by the cardiac base–apex axis, which is leftward in **A** and rightward in **B**.) (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

A distinction also should be drawn between single and common, as applied to cardiac chambers and valves. *Single* implies that the corresponding contralateral structure is entirely absent. Tricuspid atresia with a single-inlet ventricle is one example. In contrast, the term *common* indicates bilateral components with absent septation. Examples are a common atrium, a common atrioventricular valve, and a common truncal artery (truncus arteriosus [TA]).

Superior Vena Cava

When the superior vena cava is single and right-sided, as normally occurs, no further designation is necessary. The term left superior vena cava is recommended for its left-sided counterpart, and distinction should be made between right-sided and left-sided structures in the setting of bilateral venae cavae. With bilateral veins, the presence or absence of a brachiocephalic (innominate) venous bridge between the two should also be described.

Inferior Vena Cava

The inferior vena cava, or at least its suprahepatic segment, almost invariably connects to the inferior aspect of the

morphologic right atrium. Rarely, and usually in patients with polysplenia, this connection is interrupted, and the vein empties into the superior vena cava through a direct connection with the azygos or hemiazygos vein, representing azygos continuation of the inferior vena cava. In such cases, the hepatic veins generally connect directly to one or both atria via the suprahepatic segment of the inferior vena cava (9).

Coronary Sinus

The coronary sinus normally joins the right atrium. Rarely, its ostium is atretic. Moreover, variable portions of the vein may be unroofed and produce a left atrial fistula. Complete unroofing is commonly referred to as absence of the coronary sinus and may be associated with asplenia syndrome and direct left atrial connection of a left superior vena cava, or may be an isolated anomaly with resultant creation of an atrial septal defect of coronary sinus type.

Pulmonary Veins

Normally, the four pulmonary veins join the body of the left atrium separately. As a variant of normal, the upper and lower

veins, most commonly from the left lung, merge and connect to the left atrium as a single vein. Another variant is independent connection of the right middle lobar vein directly to the left atrium.

In the setting of anomalous pulmonary venous connection or severe left-sided obstructive lesions, a vessel connecting the pulmonary veins to the left brachiocephalic, or innominate, vein has been referred to as a persistent superior vena cava, vertical vein, or a levoatrial cardinal vein. For these anomalies, perhaps the term collateral vein would suffice (analogous to collateral arteries in cases of pulmonary atresia with ventricular septal defect).

Atria

Definition

By definition, an atrium is a cardiac receiving chamber that usually is interposed between the great veins and an atrioventricular valve. Occasionally, it may exist either between the great veins and an adjacent atrium, as in tricuspid atresia or cor triatriatum (triatrial heart), or between an atrium and an atrioventricular valve, as in total anomalous pulmonary venous connection. Triatrial hearts can be described as having a subdivided left atrium, a double-chamber left atrium, or an accessory left atrial chamber. Rarely, the right atrium is subdivided by an enlarged valve of the inferior vena cava.

Right Atrium

The morphologic right atrium is characterized by connections from the venae cavae and coronary sinus and by connections to one or both atrioventricular valves, with drainage into one or both ventricles. Its septal surface is defined by an interatrial portion, with the limbus and valve of the fossa ovalis, and by an atrioventricular portion. The free wall harbors not only a large pyramidal appendage but also a crista terminalis and numerous pectinate muscles outside the appendage (11). The crista terminalis forms a boundary between the smooth-walled posterior aspect of the free wall, derived from the sinus venosus, and the muscular anterior aspect, derived from the embryologic right atrium.

Left Atrium

In contrast, the morphologic left atrium has neither a crista terminalis nor pectinate muscles other than in its appendage. This appendage is more finger shaped than pyramidal, with several small outpouchings or lobes. The main body of the left atrium is smooth walled, like the common pulmonary vein from which it is derived, and only the appendage remains as a remnant of the embryologic atrium. The body and main pulmonary veins become infiltrated by cardiac myocytes that can produce left atrial contraction. The left side of the atrial septum is entirely interatrial. Its smooth surface is interrupted only by a crescentic rim that forms the residual border of the ostium secundum.

Common Atrium

A common atrium is the result of absence, or near absence, of the atrial septum. It almost always is associated with an atrioventricular septal defect, with or without asplenia syndrome. In most cases, a characteristic band or bar of myocardium spans the midportion of the atrium as the only septal remnant. The two atrial free walls can be morphologically right and left, or they may be bilaterally right or bilaterally left.

Indeterminate Atrial Morphology

Occasionally, atrial morphology may be impossible to determine with certainty. This most often occurs in patients with right or left isomerism. With left isomerism in particular, one atrium often has a hybrid structure with some anatomic features of each atrium. In addition, previous surgical procedures with ligation of the atrial appendages or excision of the atrial septum may so distort the chambers that determination of atrial morphology is impossible.

Diagnostic Criteria

Cardiac sidedness is established by the location of the right and left atria (10) (Fig. 2.9). In this regard, anatomic landmarks in the atrial septum are useful for distinguishing between normal cardiac sidedness (*situs solitus*) and mirror-image cardiac sidedness (*situs inversus*). The limbus of the fossa ovalis always faces the morphologic right atrium. However, in the setting of atrial isomerism (*situs ambiguus*), most of the atrial septum is characteristically absent. As a result, anatomic landmarks in the atrial free walls must be used to determine cardiac sidedness. Only the parts of the free wall that are derived from the embryologic atrium are used for this purpose, not those derived from the sinus venosus or common pulmonary vein. With this in mind, the structural landmarks of a morphologic right atrium are a large pyramidal appendage, pectinate muscles, and a crista terminalis. In contrast, the hallmark of a morphologic left atrium includes only a tortuous appendage with side branches, but without pectinate muscles or a crista terminalis. Using these criteria, right and left isomerism can readily be established in most cases.

Atrioventricular Valves

Definition

Atrioventricular valves not only connect the atria to the ventricles but also serve to separate them electrically. Because these valves travel with their respective ventricles, a morphologic tricuspid valve connects to a morphologic right ventricle, and a morphologic mitral valve connects to a morphologic left ventricle. In normal hearts, viewed in a four-chamber format, the tricuspid valve ring attaches to the septum more apically than does the mitral annulus (Fig. 2.9). Identification of this arrangement by clinical imaging allows determination not only of atrioventricular valve morphology but also of ventricular morphology.

Tricuspid Valve

The normal tricuspid valve consists of three leaflets, three major commissures, and three papillary muscles. Although its annulus is elliptical (but saddle shaped), the shape of its orifice at the midleaflet (or midventricular) level is more triangular. The septal tricuspid leaflet has numerous direct cordal insertions along the ventricular septum, and the anterior leaflet forms an intraventricular curtain that separates the inflow and outflow tracts. Additionally, the tricuspid and pulmonary valves are separated by the muscular right ventricular outflow tract.

Mitral Valve

Like the tricuspid valve, the mitral valve has an elliptical (but saddle-shaped) annulus and an intraventricular anterior leaflet that separates the inflow and outflow tracts. However, the mitral valve has only two leaflets, two major commissures, and

Figure 2.9. Characteristic anatomic features of atria, atrioventricular valves, and ventricles in four specimens of normal hearts. **A:** The atrioventricular septum and the more apical attachment of the tricuspid valve ring, compared with the mitral valve, are best evaluated in a four-chamber view. **B:** The triangular tricuspid orifice and elliptical mitral orifice, at midleaflet level, are shown in a short-axis view, as are the septal insertions of tendinous cords from the septal tricuspid leaflet. **C and D:** Right-sided and left-sided features can readily be compared between a two-chamber view of the right heart (**C**) and a long-axis view of the left heart (**D**). (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

two papillary muscle groups rather than three, and because the papillary muscles attach to the left ventricular free wall, there are normally no septal insertions of tendinous cords. Moreover, in contrast to the muscular separation that exists between the tricuspid and pulmonary valves, the mitral annulus is in direct continuity with the aortic valve ring, such that the anterior mitral leaflet forms a part of the left ventricular outflow tract.

Common Atrioventricular Valve

With complete atrioventricular septal defects, the presence of a common valve, rather than distinct tricuspid and mitral valves, renders four-chamber imaging unsuitable for determining ventricular morphology. Similarly, in partial atrioventricular septal defects, the mitral valve ring generally attaches to the septum at the same level as the tricuspid annulus, producing an interatrial septal defect and interfering with the identification of ventricular morphology.

Right and Left Atrioventricular Valves

A double-inlet left ventricle is characterized by papillary muscle insertions from both atrioventricular valves into the

morphologic left ventricle. In many cases, the valves have mirror-image mitral morphology, or one of the valves (with right-ventricular straddling) has indeterminate, or hybrid, morphology with mitral and tricuspid features. Designation simply as right-sided or left-sided atrioventricular valves rather than as mitral, tricuspid, or hybrid minimizes the likelihood of confusion.

Diagnostic Criteria

The most reliable feature that allows distinction between tricuspid and mitral valves is the more apical septal attachment of the tricuspid valve when viewed in a four-chamber format (Fig. 2.9). For conditions in which this cannot be assessed, other features should be assessed, including septal cordal attachments, indicative of a tricuspid valve, and direct continuity with a semilunar valve, indicative of a mitral valve.

Ventricles

Definition

A ventricle represents an endocardial-lined chamber within the ventricular muscle mass. Other proposed definitions have been

a source of disagreement and controversy (12,13). Although normal ventricles are characterized by inlet, trabecular, and outlet regions, they are not defined by the presence of all three or by the presence of any one in particular. Hypoplastic ventricles, as described below, frequently consist of only one or two components. It is important to emphasize that, with only rare exceptions, virtually all human hearts contain two ventricular chambers. Hence, the terms single ventricle and univentricular heart are inaccurate.

Right Ventricle

A morphologic right ventricle is characterized by a heavily trabeculated anteroapical region (4). Other definitive features relate to the inlet region and the anatomic details of the tricuspid valve, as discussed earlier. The normal right ventricular outflow tract (infundibulum or conus) represents a collar of muscle that separates the tricuspid and pulmonary valves. Rarely, in the case of a double-outlet left ventricle, the infundibular region may originate entirely from the contralateral ventricle. To conceptualize this and other conotruncal anomalies, the heart may be considered as consisting of five chambers (two atria, two ventricles, and an infundibulum) in which the infundibulum can attach to one or both ventricles, in various orientations (15).

Left Ventricle

A morphologic left ventricle has fine apical trabeculations. However, in patients with a double-inlet left ventricle, the presence of four sets of papillary muscles produces a muscular apex that can be misinterpreted as a morphologic right ventricle, particularly by echocardiography.

Common Ventricle

A common ventricle is characterized by virtual absence of the ventricular septum and by a free wall that morphologically is part right ventricle and part left ventricle. This represents an exceedingly rare condition. Accordingly, other anomalies that resemble a common ventricle should be considered before rendering a diagnosis. Among patients with a common-inlet right ventricle, the hypoplastic left ventricle may be so diminutive that it is difficult to identify even at autopsy and may lead to a misdiagnosis of common ventricle.

Ventricular Morphology

If ventricular morphology cannot be determined with confidence, the term indeterminate may be applied. This designation is usually reserved for the rare condition in which only one ventricular chamber can be identified. Such a chamber has either ambiguous morphologic features or has right and left ventricular free walls with an absent ventricular septum (a common ventricle).

Hypoplastic Ventricle

Underdeveloped ventricles have an appreciably smaller chamber size than expected, although their muscular walls may either be normal in thickness or hypertrophied, depending on the pressures generated within the chamber. Structurally, either they exhibit inlet, trabecular, and outlet components or they are deficient and consist of only one or two of these regions.

In the setting of tricuspid or mitral atresia, for example, the inlet portion of the affected ventricle is either absent or very diminutive. Similarly, with pulmonary or aortic atresia, the outlet region is usually incompletely formed. For combined tricuspid and pulmonary atresia or combined mitral and aortic atresia, the interposed ventricle is severely hypoplastic and generally consists primarily of a trabecular component.

A hypoplastic ventricle that is positioned along the antero-superior surface of the heart and gives rise to a great artery is virtually always a morphologic right ventricle. Conversely, a small chamber that occupies the posteroinferior aspect of the heart and does not connect to a great artery is almost invariably a morphologic left ventricle. Thus, the use of terms such as outlet chamber, trabecular pouch, and rudimentary chamber is probably unnecessary.

Criteria

In practice, the most reliable features that allow distinction between morphologic right and left ventricles are the nature of the apical trabeculations, the morphology of the associated atrioventricular valve, and the state of continuity between the atrioventricular and semilunar valves (Fig. 2.9). Even in the setting of a hypoplastic ventricle, the other ventricle should be assessable at all three levels. Trabeculations and valvular discontinuity can be determined angiographically, and valvular morphology and discontinuity are readily evaluated echocardiographically.

In normal hearts, the short-axis shapes and wall thicknesses of the ventricles differ appreciably. The left ventricle has a thick wall and a circular chamber, whereas the right ventricle is thin walled and more crescent shaped. Neither of these features, though, is reliable for distinguishing ventricular morphology. Right ventricular hypertrophy or left ventricular atrophy is encountered relatively frequently and produces either ventricles of similar thickness or a thick right ventricle and thin left ventricle, respectively. Likewise, straightening or leftward bowing of the ventricular septum may occur and result in mirror-image D-shaped chambers or a crescentic left ventricle, respectively.

Semilunar Valves

A semilunar valve serves to connect a ventricle to a great artery and is named according to the artery into which it empties. It is not named according to the ventricle from which it emanates or according to its relative position in the chest. Semilunar valves include aortic, pulmonary, and truncal valves. Normal semilunar valves consist of three pocket-like cusps, three commissures, and a fibrous annulus shaped like a triradiate crown. When malformed, they can have an abnormal number of cusps, be hypoplastic or dysplastic, or exhibit a combination of these features.

Great Arteries

Definition

The great arteries include the aorta, main pulmonary artery, TA, and ductus arteriosus. Distinction between the aorta, pulmonary artery, and TA is based solely on their branching patterns (Fig. 2.10); there are no other distinguishing features. In contrast, the identification of a ductus arteriosus is based on its position and its lack of tortuosity or branching.

Aorta

The aortic arch is normally left-sided, traveling over the left bronchus. In contrast, a right aortic arch travels over the right bronchus and is almost always associated with mirror-image brachiocephalic arterial branching. A double aortic arch, although rare, travels over both bronchi. The sidedness of the aortic arch is not associated with appreciable lengthening of the subclavian bronchus and therefore does not interfere with the radiographic determination of pulmonary situs (10). Consequently, even with a right aortic arch, the length of the right bronchus will be substantially less than that of the left bronchus.

Figure 2.10. The different types of great arteries are illustrated schematically, as viewed anteriorly. A right aortic arch travels over the right main bronchus, and its brachiocephalic branching is the mirror-image of normal. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Pulmonary Artery

The mediastinal pulmonary arteries maintain their characteristic Y shape when severely hypoplastic and occasionally even when atretic. They do not branch further before entering the lungs. In addition, each artery has a unique relationship to its adjacent bronchus (Fig. 1.15 and 2.5). Rarely, the right or left pulmonary artery anomalously arises from the ascending aorta. In contrast, the smaller bronchial arteries originate from the descending thoracic aorta, often form several branches, and course along the major bronchi to enter the lungs. Systemic collateral arteries usually have a similar origin and distribution.

Truncus Arteriosus

The TA represents a common vessel that has not divided into the ascending aorta and main pulmonary artery. Accordingly, it gives rise to the coronary, systemic, and pulmonary circulations. In patients with pulmonary atresia and a ventricular septal defect, in whom no remnant of the main pulmonary artery can be identified, the single artery that emanates from the heart is an aorta and not a common TA, because the right and left pulmonary arteries do not originate from it.

Ductus Arteriosus

Embryologically, the ductus arteriosus is bilateral. The left-sided structure is simply referred to as the ductus arteriosus. It travels between the most proximal portion of the left pulmonary artery and the undersurface of the aortic arch. In the setting of a left aortic arch, a right-sided ductus arteriosus, if present, will connect the proximal portion of the right subclavian artery to the right pulmonary artery. For a right aortic arch with mirror-image brachiocephalic branching, the opposite applies. A ductus arteriosus is not tortuous and does not form branches.

POSITIONS OF CARDIAC SEGMENTS

Once the cardiac segments are defined morphologically, their spatial orientations are next recorded. Three segments are evaluated: atria, ventricles, and great arteries. The positions of the atrioventricular and semilunar valves are addressed later when segmental connections are evaluated.

Atria

The spatial relationship between the atria is important because the position of the morphologic right atrium determines cardiac sidedness (Figs. 2.3 and 2.4). If the right atrium is right-sided, then the cardiac situs is normal, or solitus. On the other hand, if it is left-sided, then the situs is mirror-image, or inversus.

Ventricles

The location of the ventricles is determined by the position of the cardiac apex and the plane of the ventricular septum. In hearts with a leftward apex, the two ventricles occupy right-anterior and left-posterior positions. Conversely, with a rightward apex, they are usually right-posterior and left-anterior. A midline apex is generally characterized by a vertical midline septum with side-by-side ventricles.

For hearts with univentricular atrioventricular connections and a hypoplastic right ventricle, the ventricular septum is often tilted midway between vertical and horizontal. Rarely, the septum is horizontal, resulting in superoinferior ventricles (upstairs-downstairs), with the morphologic right ventricle on top. Finally, in crisscross hearts with twisted atrioventricular connections, the ventricular septum may also acquire a partial

Figure 2.11. Ventricular sidedness. A, B: Right-sided ventricles. A normal right-sided morphologic right ventricle has been dissected by removal of its free wall (A). A mirror-image right-sided morphologic left ventricle is shown from a patient with atrioventricular discordance (B). C, D: Similar views are provided of a normal morphologic left ventricle (C), and a mirror-image left-sided morphologic right ventricle from a patient with atrioventricular discordance who underwent tricuspid valve replacement (D).

spiral twist, such that the relative positions of the ventricular chambers change as one travels from the cardiac base toward the apex.

In each of the aforementioned positions, the ventricles may be normal or mirror image in morphology. Mirror-image ventricles have also been referred to by various researchers as L-loop ventricles, ventricular situs inversus, or ventricular inversion (Fig. 2.11) (3).

Great Arteries

The position of the ascending aorta is generally described in relation to the main pulmonary artery (Fig. 2.12). Normal hearts are characterized by a right-posterior aorta. Abnormalities in aortic position are important to assess because each generally occurs in only a limited number of conditions. For the vast majority of malformed hearts, the aortic position is either normal or occupies a position that is dextroposed, right lateral, right anterior, or left anterior (Fig. 2.13). Only rarely are other positions encountered.

A slightly anterior shift of the aorta, to a position midway between right posterior and right lateral, is termed

dextroposition of the aorta (in contrast to dextroposition of the entire heart) and is commonly encountered in tetralogy of Fallot, double-outlet right ventricle, and atrioventricular septal defects. A right-anterior aorta is most frequently associated with complete transposition of the great arteries, and a left-anterior aorta most often occurs in patients with either congenitally corrected transposition of the great arteries or a double-inlet left ventricle.

CONNECTIONS OF CARDIAC SEGMENTS

Once the morphology and positions of the cardiac segments are determined, the manner in which they join to one another can be evaluated. Connections exist at three levels: venoatrial, atrioventricular, and ventriculoarterial. Abnormal venoatrial connections are related to malformations involving the sinus venosus, common pulmonary vein, and their derivatives.

In contrast, cardiac valves form the mortar that connects atria to ventricles and ventricles to great arteries. These connections, however, do not necessarily imply patency for blood flow. For example, in aortic atresia, identification of

Figure 2.12. The possible positions of the ascending aorta relative to the main pulmonary artery are shown schematically, as viewed from below (from apex toward base).

an imperforate valve between the left ventricle and the ascending aorta is indicative of a concordant connection, despite the fact that blood does not flow between the two. The presence of overriding valves can interfere with the determination of atrioventricular and ventriculoarterial connections, as discussed below.

Venoatrial Connections

Normally, the superior and inferior venae cavae and the coronary sinus connect to the morphologic right atrium and the pulmonary veins join the morphologic left atrium. Anomalies may involve the systemic veins, pulmonary veins, or both, and they can involve all or only some of the veins. Consequently, the connection of each venous structure should be evaluated separately.

Atrioventricular Connections

Only four possible modes of atrioventricular connection exist: concordance, discordance, univentricular, and ambiguous (Figs. 2.4B, 2.14, and 2.15). The univentricular connections, in turn, include three subtypes: double inlet, single inlet, and common inlet.

If an atrioventricular valve is atretic, it is important to distinguish between the presence of an imperforate fibrous membrane, in which the connection can be determined, and absence of the atrioventricular connection on that side of the heart. Most cases of tricuspid atresia, for example, are characterized by an absent right atrioventricular connection rather than by an identifiable valvular plug. By clinical imaging, the membranous septum should not be misinterpreted as an imperforate tricuspid valve.

Concordance and Discordance

Concordance denotes the normal state and indicates that the morphologic right atrium is connected to the morphologic

right ventricle and that the left atrium is connected to the left ventricle. In contrast, connection of the right atrium to the left ventricle and of the left atrium to the right ventricle constitutes atrioventricular discordance, which corresponds to ventricular inversion or L-loop ventricles.

Univentricular Atrioventricular Connections

When both atria are joined to only one ventricle, the connection is univentricular, and three variants are recognized: double-inlet ventricle, in which two atrioventricular valves are present; single-inlet ventricle, in which only one valve is present and there is no grossly identifiable remnant of the other valve; and common-inlet ventricle, in which a common atrioventricular valve connects both atria to only one ventricle. Thus, it is the connection, and not the heart, that is univentricular.

Ambiguous Atrioventricular Connection

With either right or left cardiac isomerism, the atrioventricular connection, by definition, is ambiguous or mixed. In the setting of right isomerism, for example, the right-sided morphologic right atrium might be connected to a morphologic right ventricle (concordance), and the left-sided morphologic right atrium would then join a morphologic left ventricle (discordance). For complex cases such as this, a description of the atrioventricular connection is recommended.

Ventriculoarterial Connections

Like connections at the atrioventricular level, those at the ventriculoarterial level are limited in number. Possibilities include concordance, discordance, and double, single, and common outlets (Figs. 2.16 and 2.17). Occasionally, with an atretic pulmonary or aortic valve, the ventricle to which the corresponding great artery is connected cannot be distinguished with certainty, and the ventriculoarterial connection is considered indeterminate.

Concordance and Discordance

Concordance refers to the normal state, in which the morphologic right ventricle is connected to the pulmonary artery and the morphologic left ventricle is linked to the aorta. By comparison, discordance corresponds to right ventricular origin of the aorta and left ventricular origin of the pulmonary artery and is synonymous with transposition of the great arteries.

When the atrioventricular connection is concordant and the ventriculoarterial connection is discordant, the malformation is called complete transposition, which results in complete separation of the systemic and pulmonary circulations, except at the sites of shunts. In contrast, congenitally corrected transposition is characterized by ventriculoarterial discordance and atrioventricular discordance, which results in normal blood flow but a systemic workload on the morphologic right ventricle. Because the term great vessels refers to either the great arteries or the great veins, use of the term great arteries is favored for the transposition complexes.

Double, Single, and Common

When both great arteries emanate from only one ventricular chamber, the ventriculoarterial connection is considered double outlet. It is important to recognize that a double-outlet connection is not synonymous with the diagnostic entity known as double-outlet right ventricle. This form of connection includes not only double-outlet right ventricle but also double-outlet left ventricle and most cases of tetralogy of Fallot.

Figure 2.13. Aortic positions in four types of congenital heart disease. **A:** The aortic position is normal in this example of supra-ventricular aortic stenosis with bilateral superior venae cavae. **B:** A right lateral aorta is associated with tetralogy of Fallot and a right aortic arch with mirror-image brachiocephalic branching. **C:** The aorta is right-anterior in this case of complete transposition of the great arteries. **D:** The aortic position in this patient is left-anterior and is associated with a double-inlet left ventricle. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 2.14. The six possible atrioventricular connections are shown schematically. **Upper panel:** Concordance is synonymous with the normal state, and discordance is synonymous with ventricular inversion. For either right or left cardiac isomerism, the atrioventricular connection is always ambiguous. **Lower panel:** There are three possible univentricular atrioventricular connections: double inlet, single inlet, and common inlet. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 2.15. Four types of atrioventricular connection, shown in a four-chamber (or three-chamber) format. **A:** Concordance. **B:** Discordance. **C:** Double-inlet left ventricle. **D:** Tricuspid atresia with single-inlet left ventricle and absent right atrioventricular connection (arrows). (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 2.16. The five possible ventriculoarterial connections are shown schematically. **Upper panel:** Concordance indicates the normal state, and discordance is synonymous with transposition of the great arteries. **Lower panel:** There are three other possible connections: double outlet, which usually involves a right ventricle; single outlet, which includes pulmonary atresia with ventricular septal defect; and common outlet, which represents TA. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 2.17. Four types of ventriculoarterial connection, viewed anteriorly. **A:** Discordance, in complete transposition of the great arteries. **B:** Double-outlet connection, in double-outlet right ventricle. **C:** Single-outlet connection, in pulmonary atresia with a ventricular septal defect and ductal origin of the pulmonary arteries. **D:** Common-outlet connection, in TA. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Morphologic criteria exist to distinguish tetralogy of Fallot from cases of double-outlet right ventricle with subpulmonary stenosis and a subaortic ventricular septal defect. Interestingly, patients with tetralogy of Fallot and a complete atrioventricular septal defect usually have Down syndrome and a low surgical mortality rate, whereas those with double-outlet right ventricle and a complete atrioventricular septal defect characteristically have atrial isomerism and a high surgical mortality rate.

Among patients with pulmonary atresia and a ventricular septal defect, there exists a group in whom no remnant of the pulmonary valve or proximal portion of the pulmonary artery can be identified. As a result, only the aorta arises from the ventricles, constituting a single-outlet ventriculoarterial connection. In general, this situation does not pertain to aortic valve atresia because the ascending aorta, although hypoplastic, must remain patent to provide coronary blood flow, thus allowing its ventricular connection to be readily determined.

A common-outlet connection is characteristic of TA, in which this vessel represents the undivided aortic and pulmonary roots. Although hearts with single-outlet and common-outlet connections are quite similar, only in the setting of TA do the pulmonary arteries arise proximally from this vessel rather than from the ductus arteriosus or systemic collateral arteries.

Overriding and Straddling Valves

Definition of Overriding Valves

Overriding may be defined as biventricular emptying of an atrioventricular valve or biventricular origin of a semilunar valve.

It is a property of the valve annulus and is always associated with a malalignment ventricular septal defect. The presence of annular overriding may interfere with accurate determination of cardiac connections. As a further complication in living patients, the extent of overriding may vary throughout the cardiac cycle and may appear to vary with different angles of view.

Malalignment

For overriding atrioventricular valves, the atrial and ventricular septa are malaligned. This may represent a lateral shift, a rotational shift, or a combination of the two (Fig. 2.18). The ventricular septal defect tends to involve the basal portion of the inlet septum. For the assessment of atrioventricular connections, an atrium is considered to join the ventricle into which >50% of the valve orifice empties (Fig. 2.19). A common atrioventricular valve is usually associated with concordant or discordant connections, although a common-inlet arrangement applies if >75% of the valve orifice empties into only one of the two ventricles.

Overriding of the semilunar valves is associated with malalignment of the outlet septum relative to the remainder of the ventricular septum. Malalignment can be lateral, rotational, or a combination of these (Figs. 2.18 and 2.20). The ventricular septal defect is located beneath the overriding artery and is either membranous or outlet in location, or a combination of the two. As with the atrioventricular valves, the 50% rule also applies to the semilunar valves (Fig. 2.21).

Figure 2.18. The types of annular overriding and septal malalignment are illustrated schematically. **Upper panel:** Atrioventricular valves are shown, with lateral and rotational malalignments between the atrial and ventricular septa. **Lower panel:** Semilunar valves are shown, with lateral and rotational malalignments between the ventricular and outlet septa. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 2.19. The effect of overriding atrioventricular valves on the determination of atrioventricular connections. **Upper panel:** With progressive leftward shifting of the atrial septum, the connections change from concordant to double-inlet left ventricle. **Lower panel:** The two insets illustrate the 50% rule. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 2.20. Overriding semilunar valves, in two cardiac specimens. **A:** An overriding aortic valve in tetralogy of Fallot. **B:** An overriding pulmonary valve in complete transposition of the great arteries. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 2.21. The effect of overriding semilunar valves on the determination of ventriculoarterial connections. **Upper panel:** With progressive rightward shifting of the outlet septum, the connection changes from concordant to double-outlet right ventricle. **Lower panel:** The two insets illustrate the 50% rule. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Definition of Straddling Valves

In contrast to annular overriding, *straddling* involves the anomalous insertions of chordae tendineae (tendinous cords) or papillary muscles into the contralateral ventricle (Figs. 2.22 and 2.23). Thus, straddling involves only the atrioventricular

valves and requires the presence of a ventricular septal defect. Although straddling does not affect the evaluation of atrioventricular connections, it is important that it be identified preoperatively because its presence may preclude certain types of surgical repair or may necessitate valve replacement. Cordal straddling may occur alone or in conjunction with annular overriding.

Figure 2.22. Overriding and straddling atrioventricular valves are shown schematically. **Upper panel:** Overriding and straddling are compared (see text for definitions). **Lower panel:** The three types of straddling are determined by the sites or cordal insertion into the contralateral ventricle along the crest (type A) or body (type B) of the ventricular septum, or onto the ventricular free wall (type C). (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Figure 2.23. Overriding and straddling atrioventricular valves in two specimens. **A:** Straddling without overriding of the left-sided tricuspid valve (arrows) in a heart with atrioventricular discordance. **B:** Overriding and straddling of both atrioventricular valves is associated with rotational malalignment of the atrial and ventricular septa in a case of superoinferior ventricles with a horizontal ventricular septum. (See Appendix 1.1 at <http://solution.lww.com> for abbreviations.)

Development of Myocardial Structure and Function

Pamela A. Lucchesi ■ Kirk R. Hutchinson ■ Luciana Martins ■ Loren E. Wold

The structure and function of the myocardium undergoes dynamic changes during fetal life and in postnatal maturation to adulthood. These processes are regulated by a number of hormones, neurotransmitters, growth factors, and mechanical forces. The development of the coronary circulation is tightly coordinated with myocardial growth to ensure an adequate supply of oxygen and metabolic substrates. A complete understanding of the physiologic processes that regulate myocardial structure and function is a necessary prerequisite to understand the pathogenesis of congenital and acquired heart disease. This chapter describes the developmental changes in cardiac structure and excitation–contraction (E–C) coupling along with cell–cell and cell–matrix interactions at the cellular and tissue levels. Postnatal changes in autonomic innervation are summarized. The effects of these changes on myocardial systolic and diastolic dysfunction are also discussed.

It is important to note that the majority of studies on developmental changes in myocardial structure and function have been performed in zebra fish, chick embryos, and rodents, with some additional data taken from higher mammals and humans. While the process of E–C coupling is very similar, there is significant spatiotemporal variability in structural development across mammalian species. Unless otherwise noted, the majority of the developmental changes described in this chapter focus on data from rodent models and humans. Second, most of our understanding of developmental changes in myocardial structure and function is limited to the left ventricle (LV), especially during the postnatal period. Finally, many important concepts and molecular mechanisms have been omitted because they are beyond the scope of this chapter.

MYOCARDIAL STRUCTURE

The heart is a complex organ composed of multiple cell types that can be grouped into conducting, supporting, and functional cells (Fig. 3.1). The cellular constituents of the heart include cardiac myocytes, cardiac fibroblasts, endothelial cells, and vascular smooth muscle cells. The conducting cells are mainly Purkinje fibers that propagate the action potential from the atrium to the ventricle. Purkinje fibers are responsible for rapid communication and propagation of the signal throughout the heart. While cardiac myocytes are responsible for the mechanical function of the heart, they comprise only approximately 30% of the total number of cells. Cardiac fibroblasts predominate in conferring structural integrity to the heart (1). Dynamic cross talk between cardiac myocytes and cardiac fibroblasts plays a crucial role in myocardial development and structural remodeling.

CARDIAC FIBROBLASTS AND THE EXTRACELLULAR MATRIX

The cardiac fibroblast is the most abundant noncardiac myocyte cell type present within the postnatal mature heart. Cardiac fibroblasts play an extensive role in cardiac development and remodeling. They are the main cell types responsible for the deposition of extracellular matrix (ECM) proteins and also dynamically remodel the ECM through the secretion of matrix metalloproteinases and their tissue inhibitors. Fibroblasts also act as a source of growth factors, mitogens, and cytokines that signal to neighboring myocytes. Cardiac fibroblasts are derived from different cell lineages at different developmental stages. During embryonic development, they are mesenchymal in origin and are derived from the proepicardial organ. Fibroblasts also arise from the differentiation of bone-marrow-derived circulating fibrocytes (2). In the neonatal and adult heart, cardiac fibroblasts arise from resident cells via epithelial–mesenchymal transformation and from bone-marrow-derived cells (3).

The ECM provides structural support to the heart, facilitates mechanical and chemical signaling during myocardial development, and helps to maintain normal homeostasis in the adult heart in response to physiologic stressors and injury. Components of the ECM include interstitial collagens, elastin, fibronectin, proteoglycans, glycoproteins, cytokines, growth factors, and proteases. The most abundant extracellular collagens are the fibrillar collagens, type I and III. Elastic fibers are present in close association to collagen and are responsible for maintaining normal elasticity of the cellular framework. Fibronectin influences cellular properties, including cellular growth. Proteoglycans and glycoproteins appear to play a role in signaling and ECM turnover and serve as a reservoir for latent growth factors (e.g., transforming growth factor (TGF)- β , epidermal growth factor).

The collagen network of the myocardium begins forming during fetal development (3). Cardiac fibroblasts become enmeshed in this network, which allows them to contract the endomysial collagen, exerting mechanical force on the myocytes (Fig. 3.2). In addition, this organization allows fibroblasts to maintain structural integrity of the heart through cell–cell and cell–ECM interactions, as well as through proliferation and ECM degradation and synthesis. In the adult myocardium, this network includes the epimysium that surrounds large groups of muscle fibers, the perimysium arising from the epimysium that surrounds smaller groups of muscle fibers, and the endomysium that tethers individual fibers to each other and the adjacent vasculature (4,5). In addition to acting as scaffolding for cells and vessels, the collagen network also coordinates the delivery of force generated by myocytes, serving as a viscoelastic medium facilitating compression and recoil properties of the tissue (6).

Cardiac fibroblasts are regulated by mechanical and molecular signals during cardiac development. Mechanical

Figure 3.1. Schematic representation of the major cell types of the heart, including myocytes, fibroblasts, blood vessels, and nerve terminals. (Modified from Baudino T.A., et al. Cardiac fibroblasts: friend or foe? *Am J Physiol Heart Circ Physiol* 2006;291:H1015-H1026.)

stimulation of fibroblasts causes a marked increase in integrin receptors and secretion of ECM proteins, cytokines, and growth factors. Angiotensin, endothelin, and TGF- β also stimulate matrix deposition, while the inflammatory cytokines such as interleukin 1- β and tumor necrosis factor- α inhibit matrix deposition and promote matrix degradation by matrix metalloproteinases (7).

Basement Membrane

A specialized area of the matrix termed the basement membrane or basal lamina surrounds all cells in the myocardium except

cardiac fibroblasts. The primary components of the basal lamina are laminin, type IV collagen, and the proteoglycan perlecan. Type IV collagen assembles into a sheet-like mesh and provides tensile strength. Type IV collagen is coated by perlecan that binds to integrins and dystroglycans on the plasma membrane to stabilize the basement membrane structure against mechanical forces. Perlecan is expressed at high levels throughout embryogenesis in the heart where it is required to ensure mechanical stability until cell-cell contacts have formed and matured (8). Cardiac deletion of perlecan encoded by *HSPG2* in mice is lethal to the embryo due to basement membrane deterioration, blood leakage into the myocardium, and cardiac asystole (9).

Figure 3.2. Connective tissues of the human heart (transverse section). **A:** The collagen network around cardiomyocytes and small vessels is clearly observed. *Thick arrow:* perimysium; *thin arrow:* endomysium). **B:** The interstitial connective tissue consisting of perimysial and endomysial components presents a honeycomb shape. The perimysium (*thick arrow*) surrounds groups of cardiomyocytes, and the endomysium (*thin arrow*) surrounds each cardiomyocyte. **C:** The endomysium supports and connects individual cardiomyocyte fascicles. **D:** At higher magnification, collagen fibers show interconnections on the surface of cardiomyocytes. Thin collagen strands are probably collagen III (*arrow*). Scale bar = 3 μm ; magnification $\times 10,000$. (From Kanzaki Y, Terasaki F, Okabe M, et al. Three-dimensional architecture of cardiomyocytes and connective tissue in human heart revealed by scanning electron microscopy. *Circulation* 2010;122:1973–1974, with permission.)

CARDIAC MYOCYTES

Cardiac myocytes have two major mechanistic functions: force generation by myofibrils in response to E–C coupling and force transmission across cell bundles mediated by the integration of electromechanical signals at the intercalated disc. Myocytes also communicate with the ECM and other cardiac cells through costameres.

Plasma Membrane

The plasma membrane (or sarcolemma) is the region of the cell that contains ion pumps, channels, and exchangers that contribute

to action potential propagation as well as maintenance of proper ionic and chemical gradients. The flow of ions controlled by these proteins is essential for proper myocyte function and directly regulates cellular contraction and relaxation. Numerous G-protein-coupled receptors and cytokine and growth factor receptors are located on the plasma membrane and are responsible for transducing changes in the local neurohormonal milieu into intracellular signals that regulate cell growth and function.

Na⁺- and K⁺-ATPases and Exchangers

The Na⁺/K⁺-ATPase maintains the ionic gradient across the sarcolemmal membrane by pumping Na⁺ out of the cell and

K⁺ into the cell against their respective concentration gradients. Since under physiologic conditions, three Na⁺ are removed from the cell but only two K⁺ are taken up per pump cycle, the ATPase generates a small outward current. Both the maintenance of the ionic gradient and the electrogenic property of Na⁺/K⁺-ATPase are required to maintain resting Ca²⁺ levels (10).

The Na⁺/K⁺-ATPase is composed of α - and β -subunits. The α -subunit contains the binding sites for ATP, Na⁺, K⁺, and cardiac glycosides, and is thus largely responsible for the catalytic, transport, and pharmacologic characteristics of the ATPase. The smaller β -subunit modulates the transport characteristics of the ATPase and plays an important role in its proper membrane insertion (10). There are three Na⁺/K⁺ pump α -subunits in the heart that display similar ion affinities and ATPase activity, but different affinities for cardiac glycosides and distinct subcellular localizations. In the rodent heart, the low-digitalis affinity α_1 isoform predominates through all phases of development, while there is a postnatal transition from the neonatal α_3 isoform to the adult α_2 isoform that occurs within the second week of postnatal life (11). However, in humans, the α_1 isoform has high affinity for cardiac glycosides. Three different isoforms of the Na⁺/K⁺-ATPase in the adult human heart, $\alpha_1\beta_1$, $\alpha_2\beta_1$, and $\alpha_3\beta_1$, are expressed with different affinities for various cardiac glycosides (12). To date, there have been no human studies characterizing developmental changes in Na⁺/K⁺-ATPase isoform expression.

Na⁺/K⁺-ATPase activity indirectly regulates other plasma membrane transporters that require an inward Na⁺ gradient. The cardiac Na⁺/Ca²⁺ exchanger (NCX1) is the major Ca²⁺ extrusion mechanism in cardiac myocytes. It functions by utilizing the Na⁺ electrochemical gradient to mediate the electrogenic countertransport of three Na⁺ ions for one Ca²⁺ ion across the sarcolemmal membrane (13). This exchanger is bidirectional and capable of moving Ca²⁺ in either direction across the sarcolemma.

The plasma membrane also contains a high-affinity, low-capacity Ca²⁺-ATPase that extrudes Ca²⁺ from the cell in an ATP-dependent process. This pump functions as a fine-tuner of cell Ca²⁺, lowering it to the submicromolar level (14), thereby maintaining low amounts of intracellular Ca²⁺ during basal conditions.

Na⁺ Channels, Ca²⁺ Channels, and K⁺ Channels: The Cardiac Action Potential

Under resting conditions, the membrane potential (V_m) is set by the intracellular and extracellular concentrations of Na⁺ and K⁺ and the conductance properties of ion channels on the plasma membrane (Fig. 3.3). This equilibrium potential (voltage at which there is no net flow) for a single ion is described by the Nernst equation. In ventricular myocytes, the resting V_m (~−86 mV) is close to that predicted by the Nernst equations for K⁺ (15). In order to elicit an action potential, any electrical stimulus must depolarize the membrane to a threshold value (~−65 mV) – the lowest membrane potential that causes activation of voltage-sensitive Na⁺ channels.

Phase 0: The rapid depolarization phase and action potential amplitude is due to Na⁺ entry through voltage-sensitive Na⁺ channels encoded by the SCN5A gene. Once open, these channels rapidly inactivate at higher V_m and undergo a refractory period in which the channels become unresponsive to any further stimulation. This voltage-dependent activation and inactivation of the channel are important clinically since changes in its expression or gating properties can change action potential amplitude and durations, leading to arrhythmias (15). For

Figure 3.3. Schematic representation of the cardiac action potential.

example, gain-of-function mutants in SCN5A prolong the action potential duration and are one cause of long Q-T syndrome (16). Loss-of-function mutants decrease the inward Na⁺ current and are associated with Brugada syndrome, a disorder characterized by susceptibility to ventricular arrhythmias in structurally normal hearts that may cause syncope or sudden death (17).

Phase 1: Early repolarization. The brief repolarization phase results in the notch between the end of the upstroke and the beginning of the plateau phase. This transient outward current is largely due to activation of K⁺ channels. There are numerous K⁺ channels present in the sarcolemma that are characterized by their gating properties and substances that regulate their opening (e.g., K_{ACh} , K_{Ca}) and closing (e.g., K_{ATP}) (18). The K⁺ channels involved in this phase are outward rectifier K_v channels.

Phase 2: The plateau phase. Ca²⁺ enters the cell through voltage-gated L-type Ca²⁺ channels, which are composed of two subunits (α and α_1) that form the ion pore. These channels are regulated by membrane potential and the inward Ca²⁺ concentration gradient. In the adult heart, the majority of Ca²⁺ influx occurs through this channel, although fetal myocytes also express T-type Ca²⁺ channels that may contribute to E–C coupling. During this phase, delayed outward rectifier K⁺ channels begin to open and the positive V_m drives K⁺ efflux from the cell.

Phase 3: K⁺ efflux through outward rectifier K⁺ channels and Ca²⁺-activated K⁺ channels (K_{Ca} or BK channels) dominates this repolarization phase. Mutations in the KCNQ1 gene encoding a delayed rectifier K⁺ channel are also associated with long QT syndrome (19). On the other hand, activation of the K_{Ca} channel by Ca²⁺ explains why the QT interval is diminished by cardiac glycosides (15). Expression of these channels changes over the course of cardiac development, which likely influences changes in the action potential duration and repolarization (20,21).

Phase 4: Restoration of ionic concentrations: This phase is largely driven by K⁺ flux through inwardly rectifying K⁺ channels. The Na⁺/K⁺-ATPase also maintains the resting membrane potential.

Sarcoplasmic Reticulum

The sarcoplasmic reticulum (SR) is a network of tubular membranes that surround the myofibrils and are involved in the regulation of Ca²⁺ concentrations (Fig. 3.4). The SR is composed of two distinct regions that are involved in Ca²⁺ regulation: the junctional SR regulates Ca²⁺ storage

Figure 3.4. Pumps and channels regulate Ca²⁺ signaling, the key modulator of contraction and relaxation. Following depolarization, Ca²⁺ enters the cells through the sarcolemma and causes Ca²⁺-induced Ca²⁺ release from the SR, initiating contraction. Relaxation occurs when most of the Ca²⁺ is resequenced into the SR. SR, sarcoplasmic reticulum; SL, sarcolemma; PLB, phospholamban; NCX, Na–Ca exchanger.

and release, while the longitudinal SR regulates Ca²⁺ uptake. Release of SR Ca²⁺ is a tightly regulated process, and proper functioning of the SR is imperative for normal heart function. The SR contains ryanodine Ca²⁺ release channels that play a primary role in E–C coupling (22) (see below). The cardiac SR Ca²⁺-ATPase (SERCA2a) pumps Ca²⁺ into the SR against its concentration gradient. SERCA2a is the main player in restoring diastolic Ca²⁺ levels and terminating Ca²⁺-dependent force activation. The function of SERCA2a can be modulated by several indirect and direct factors. The most predominant indirect mechanism is inhibition by the phosphoprotein phospholamban. Phosphorylation of phospholamban via β -adrenergic stimulation and enhanced cAMP-dependent protein kinase A activity (PKA) relieves SERCA2a inhibition (23). SERCA2a is also under the direct control of Ca²⁺/calmodulin-dependent protein kinase II, which has been shown to phosphorylate SERCA2a and enhance its Ca²⁺ transport capacity (23). During development, the SR content of the heart changes wherein the immature heart SR content is dramatically less (24,25) than in the mature heart (26).

T-Tubules

The system of T-tubules extends transversely into the center of the myocyte and envelops the myofibril at the level of the Z-disk, forming couplings with the SR. This allows transmission of the action potential to the cellular interior, leading to rapid activation of the cell. In humans, T-tubules are noted at 30 weeks gestation (27). The development of T-tubule net-

works appears variable, with myocytes from animals that are well developed at birth having well-developed T-tubule systems and those from less well-developed neonates lacking mature T-tubule networks. These variations in T-tubule development may account for the variability in E–C coupling between mature and immature heart cells.

Sarcomere

The sarcomere (Fig. 3.5), or the functional unit of heart muscle, is defined as the region between two Z-lines and is composed of thick (myosin) and thin (actin) filaments. The regions of the sarcomere include the I-band, which contains thin filaments, troponin, and tropomyosin; the A-band, which is a region of overlapping thick and thin filaments; and the M-band (located in the center of the A-band) containing thick filaments linked to titin and myosin-binding protein.

Thin Filaments

The thin filaments are composed of two strands of actin monomers. There are two isoforms of actin, skeletal and cardiac α -actin, that differ by four amino acids. Early in human heart development, both α -actin isoforms are expressed (28). As development progresses, however, the content of skeletal α -actin is decreased, while the cardiac isoform is increased; however, the mechanisms of this isoform switch have not been delineated. The Tn complex is composed of three proteins: TnT, TnI, and TnC (29). TnT facilitates binding of the

Figure 3.5. Protein composition of the sarcomere. Titin, extending from the Z band to the thick filament, connects to myosin by myosin-binding protein C. Several proteins support the thin filaments, including nebulin (connecting the thin filaments to the Z band) and tropomodulin (linked to the ends of thin filaments). (Redrawn from Katz AM. *Molecular and Cellular Basis of Contraction and Relaxation*. Figure 1-8. In: Colucci WS, ed. *Atlas of Heart Failure: Cardiac Function and Dysfunction*. 4th ed.)

troponin complex to tropomyosin. TnI is a strong inhibitor of actin–myosin interactions, binding to TnC during systole and actin during diastole (Fig. 3.6) (30). TnT is involved in binding the troponin complex to tropomyosin. Tropomyosin is evident in both α and β isoforms that wind together to form a coil. TnI is a strong inhibitor of actin–myosin interactions, whereby TnI binds to TnC during systole and actin during diastole. TnI also has skeletal and cardiac forms, and both are expressed in immature hearts (31). During development of the heart, the skeletal isoform is changed to the cardiac isoform,

Diastole

Figure 3.6. Interaction of the troponin–tropomyosin complex with an actin filament. During diastole, troponin I covers the adenosine triphosphate (ATP)-reactive site on the actin filament. When Ca^{2+} binds to troponin C during systole, a conformational change causes TnT to lift tropomyosin and TnI away from the ATP-reactive site to permit actin–myosin interaction. (Redrawn from McBride BF, White CM. *Levosimendan: Implications for Clinicians*. *J Clin Pharmacol* 2003;43:1071–1081, with permission.)

which could help to explain the changes in cardiac function during development (32,33). TnC binds Ca^{2+} and a conformational change causes TnT to lift tropomyosin and TnI away from the ATP-reactive site to permit actin–myosin interaction leading to contraction.

The distribution of thin filament subunits is altered during heart development and likely contributes to developmental changes in myocardial contraction. The regulation of TnI has been well studied in the heart and has two isoforms, cardiac TnI and slow skeletal TnI. Slow skeletal TnI is the major isoform during development, and a switch occurs at birth to cardiac TnI (34,35). This switch is postulated to account for the decrease in calcium sensitivity found in the adult heart as compared to the neonatal heart (33). TnT has multiple isoforms. Studies in the rat heart have demonstrated that TnT1 is a major isoform in the fetal heart with a switch to TnT2 in the neonate (36), but in human studies, TnT1 is a predominant isoform in both the fetus and adult, while TnT2 is only found in the fetal heart (30). Interestingly, TnC does not seem to change expression during development.

Changes in actin and tropomyosin also occur during development. In the fetus, the predominant actin isoform is α -skeletal actin and this is replaced by α -cardiac actin in the adult heart (37). Tropomyosin also has two major isoforms, α and β . In the adult heart, these two forms are present at approximately equal levels, but during development β -tropomyosin has lower expression levels. During late fetal development, expression of this β isoform increases to adult levels and this is postulated to be inversely correlated with heart rate (37).

Thick Filaments

Myosin is the most abundant protein in the myocyte, with two heavy chains and four light chains. The two heavy chains of myosin wind together to form the thick filament, with the myosin heads projecting up from the long axis of the thick filament to form cross-bridges. In the presence of Ca^{2+} , the myosin heads bind to actin to initiate contraction. In the first step, the myosin head, due to its intrinsic ATPase activity, becomes activated by ATP hydrolysis, allowing the head to attach to

actin and form a cross-bridge. The interaction elicits a conformational change in the myosin head that pulls the actin filament inward (“power stroke”). ADP is then released and a new molecule of ATP binds to the myosin head, causing it to release the actin filament. If intercellular Ca^{2+} remains elevated, myosin will undergo another cross-bridge cycle.

Myocytes contain two types of myosin heavy chain (MHC): α -MHC and β -MHC. Detailed expression studies in mouse embryos demonstrate that the predominant isoform in the developing ventricles is MHC- β , while MHC- α expression is localized to the developing atria. MHC- β is found as early as E7.5 in the mouse embryonic heart (38). In early postnatal life in the rodent, there is a switch from MHC- β to MHC- α in the ventricles. Recent studies demonstrate the role of the microRNA miR-208 in regulating this switch and that miR-208 mediates the effects of thyroid hormones (THs), which are known to affect MHC- α and MHC- β expression levels (39).

In human ventricles, β -MHC is the predominant form during all stages of life (40). Interestingly, α -MHC is found in only very small amounts in the human ventricle, but mutations in this protein are linked to both hypertrophic and dilated cardiomyopathy (41). Expression of the myosin light chain (MLC) does not appear restricted in the early to midfetal stages of development, but by late fetal life, MLC1A is restricted to the atria and MLC1V to the ventricles. This expression is maintained in adulthood.

Myosin-binding protein C is a protein associated with the thick-filament myosin that is found within the A band and functions as a tether to hold the thick filaments together. Mutations in myosin-binding protein C have been linked to hypertrophic cardiomyopathy (42,43) and may account for potential alterations in cardiac contractile function during development (44).

Z-disk

The Z-disks demarcate individual sarcomeres and directly interact with all myofilament proteins except myosin. α -Actinin is the primary protein that makes up the backbone of the Z-disk and cross-links the ends of actin to adjacent sarcomeres (45). Proteins in the Z-disk also bind the intermediate filament desmin to link the sarcomere to the intercalated disc and costameres at the plasma membrane (see following section). This unique structure allows the integration of signals from the cytoskeleton, ECM, and those induced by mechanical stress (45).

Titin

Titin is the largest protein known, spanning half of the sarcomere from Z-disk to M-band (Fig. 3.5). Titin's remarkable elasticity is due to its I-band domain that is composed of three sequence elements that develop passive tension as the sarcomere is stretched. These three elements are composed of distal and proximal Ig segments, a unique N2B segment, and the PEVK segment (named for its rich composition of proline [P], glutamate [E], valine [V], and lysine [K] residues). Tension generated by these elements is responsible for pressure generated during diastole and accounts for approximately 80% of passive pressure at physiologic sarcomere lengths (46). Titin's passive force is modulated during development and in response to pathologic changes in hemodynamic load. This occurs primarily by differential splicing primarily in the Ig and PEVK segments, which leads to three different isoform classes with variable compliance (47). The stiffer N2B isoform is the shortest of these and is approximately 3 MDa. The second class is the more compliant N2BA isoform, which is approximately 3.3 to 3.5 MDa, and contains additional PEVK segments and a varying number of additional Ig domains.

The relationship of titin to cardiac development and disease is complex. A dramatic isoform switch occurs during cardiac development in mammals, from fetal N2BA titin expressed before birth to a mix of smaller N2BA/N2B isoforms found postnatally. Adult rat hearts almost exclusively have N2B titin isoform (48,49). These changes in titin isoform composition during heart development affect myofibrillar extensibility, passive force generation, and alter cardiac stiffness (50). In humans, N2BA/N2B ratios vary with disease from an increased ratio in dilated cardiomyopathy (more compliant) (46,51–53) to decreased ratios in aortic stenosis (less compliant) (46,52–54).

MITOCHONDRIA AND METABOLISM

As the heart develops, it requires an abundant amount of energy to grow, differentiate, and mature. Cellular mitochondria are the key “powerhouses” of energy production, generating abundant amounts of ATP for use in cellular processes. Relative to other organs, the heart contains a high number of mitochondria to accommodate this energy need.

Mitochondria are rectangular-shaped with an inner membrane that folds into numerous compartments termed cristae. The cristae create a greatly expanded intracellular surface area to accommodate the membrane-bound enzymes of the electron transport chain responsible for generating ATP in the inner matrix. Myocytes contain two distinct types of mitochondria: subsarcolemmal mitochondria located beneath the plasma membrane and interfibrillar mitochondria located between myofibrils in parallel rows. The number, size, and volume of mitochondria increase during development (55–58), coupled with lengthening of the cristae.

The adult heart is primarily a postmitotic organ with minimal regenerative capacity. Proper functioning of cellular mitochondria is therefore critical for proper functioning of the heart. The electron transport chain is naturally somewhat “leaky,” and release of high-energy electrons from this chain generates reactive oxygen species that then react with macromolecular components of the cell (proteins, lipids, mitochondrial DNA, etc.). Though the mechanisms are not well understood, it is thought that increases in oxidative damage to cellular macromolecules due to this mitochondrial leakage play a significant role in the aging process.

Cellular metabolism and energetics undergo major shifts during the switch from fetal life to adulthood. The heart utilizes predominately glucose and lactate before birth. Following birth, there is a shift toward increased left ventricular workload. At this stage, the heart switches to fatty acids that supply reducing equivalents to the mitochondrial electron transport chain as its primary substrates for metabolism (59).

CELL–CELL AND CELL–EXTRACELLULAR MATRIX INTERACTIONS

Cell–Extracellular Matrix Interactions

Cardiac myocyte contraction causes cellular deformation and shortening (Fig. 3.7). During this process, the contractile machinery must remain connected to the surrounding ECM; otherwise, movement would be improperly transmitted, which would increase the risk of membrane damage (60). Cells maintain strong connection to the ECM through two specialized complexes, costameres and dystrophin glycoprotein complexes.

Figure 3.7. Extracellular matrix–cardiac myocyte interactions. Attachment to the ECM is mediated by costameres composed of the dystroglycan–glycoprotein complex and the integrin complex. Force transduction and intracellular signaling are coordinated through the costamere. The unique roles of each of these proteins are critical to appropriate structure and function of the heart. T-cap, titin cap; MyBP-C, myosin-binding protein C. (From Harvey PA, Leinwand LA. The cell biology of disease: cellular mechanisms of cardiomyopathy. *J Cell Biol* 2011;194:355–365.)

Costameres

Costameres are a complex protein structure that forms a physical connection between the ECM and underlying outer Z-disks of underlying sarcomeres. This complex acts to transmit the contractile forces generated by the myofilaments directly to the ECM. Members of the integrin family of transmembrane proteins are found in costameres. Integrins bind directly to specific peptide sequences in the basal lamina proteins collagen IV and laminin and to Type I and III collagens and fibronectin in the ECM. Integrins are heterodimeric proteins consisting of single α - and β -subunits. Cardiac myocytes express multiple α -subunits (α_1 -, α_3 -, α_5 -, α_6 -, α_9 -, and α_v -subunits), whereas the predominant β -subunit is β_1 and, to a lesser extent, β_{1D} (61). Different combinations of these subunits allow integrins to bind to specific ECM components. The α -subunit directly binds to the matrix proteins, while the cytoplasmic tail of β -integrin interacts with several cytoskeletal proteins (vinculin, talin, filamin) that directly link to α -actinin at the Z-disk and cytoskeletal actin. This spatial organization of integrin-associated costameres allows them to act as key mechanical sensors that transduce changes in mechanical forces to cellular signaling cascades that mediate sarcomere assembly, gene expression, cell migration, and survival. This type of “outside-in” signaling is the primary mechanism that regulates cardiac myocyte growth in response to changes in hemodynamic load (61).

Costameres play a key role in sarcomere assembly. Sustained changes in myocardial wall stress and strain result in myocyte growth or atrophy. For example, cells elongate in response to sustained diastolic strain by adding sarcomeres in series, while they thicken in response to increased systolic stress by adding sarcomeres in parallel (62). The precise mechanisms by which new sarcomeres are added to the myofilament are unknown. Russell and colleagues performed a series of gene overexpression or deletion studies in neonatal cardiac myocytes that suggest that integrins activate signaling cascades (e.g., protein kinase C- ϵ) that “loosen” the Z-disk, weakening

actin binding and stimulating actin capping and myofilament formation (62–64).

The molecular composition of integrins and the ECM changes throughout development, suggesting that these two factors may contribute to myocardial morphogenesis. One example is the coordinated regulation of fibronectin and β_1 -integrins. The levels of fibronectin and β_1 -integrin are elevated in the developing myocardium, which allow myocytes to spread and proliferate, but in adult cells that have lower levels of these proteins, myocytes only attach weakly to fibronectin. Both neonatal and adult cells bind strongly to laminin and collagen IV in the basal lamina (65).

Dystrophin-Associated Glycoprotein Complexes

The dystrophin-associated glycoprotein complex provides a strong mechanical link from the cardiac cytoskeleton to the ECM and appears to colocalize with costameres. Components of this complex include dystrophin, dystroglycan, sarcoglycans, and dystrobrevins. Mutations in these proteins result in plasma membrane damage in striated muscle as seen in muscular dystrophy-associated cardiomyopathies. Loss of normal dystrophin function in the heart produces four-chamber dilation, reduction in left ventricular function, and arrhythmias (66). Since dystrophin complex-related cardiomyopathies are covered in great detail in a later Chapter (58), this section is restricted to an overview of dystrophin complex organization and function, as well as functional classes of mutations.

Dystrophin is a rigid cytoplasmic protein that anchors dystroglycan to the cytoskeletal filamentous actin (67). Removal of dystrophin from the dystrophin glycoprotein complex makes this complex unstable and leads to its loss from the plasma membrane, rendering the cell susceptible to damage from contraction (68). Specifically, the loss of membrane integrity allows Ca^{2+} entry into the cell, which in turn activates

Ca^{2+} -sensitive proteases leading to cellular degradation and release of cardiac myocyte proteins such as creatine kinase into the bloodstream (69,70). In cardiac myocytes, mutations in dystrophin also affect the function of stretch-activated ion channels that normally open in response to stretch during ventricular filling (70).

Heterodimeric dystroglycan is a protein central to the dystrophin glycoprotein complex that spans the sarcolemma and binds to laminin in the surrounding basal lamina through its α -dystroglycan subunit and to dystrophin through the cytoplasmic, C-terminus of its β -dystroglycan subunit (71,72). Sarcoglycans are transmembrane glycoprotein complexes composed of six isoforms (α , β , δ , ϵ , γ , and ζ) that are thought to stabilize the interactions between α and β dystroglycans. Dystrobrevin binds to dystrophin and the sarcoglycan complexes and also plays an important role as a structural scaffold linking the dystrophin glycoprotein complex to intermediate filaments (73). The intermediate filaments, in turn, encircle the Z-lines of each myofibril. Mutations in dystrobrevin have been associated with left ventricular noncompaction, a recently defined cardiomyopathy characterized by a pattern of prominent trabecular meshwork and deep trabecular recesses (74).

Cell–Cell Interactions

Intercalated discs (Fig. 3.8) are highly organized and specialized components of the cardiac myocyte that maintain structural integrity and synchronized contraction of cardiac tissue. Intercalated discs are located at the longitudinal ends of the rod-shaped cardiac myocytes where contact and cell–cell communication occurs, and are composed of three different

types of connections: adherens junctions, desmosomes, and gap junctions. Adherens junctions and desmosomes provide mechanical coupling for force transmission and reinforce cardiac myocyte structure, whereas gap junctions are essential for rapid electrical transmission between cells.

Components of adherens junctions include the transmembrane cadherin (*N*-cadherin) responsible for cell–cell adhesion, the cytoplasmic catenins (α - β - γ [plakoglobin]) that bind to cadherin and regulate adhesion, and other catenin-related proteins including vinculin and α -actinin that link the intercalated discs to the cytoskeleton catenins (75). Adherens junctions hold cells tightly together as the heart expands and contracts and act as the anchor point where myofibrils are attached, enabling transmission of contractile forces from one cell to another (76). Because actin filaments also pull against cadherins, these junctions also mediate the bidirectional transmission of cytoskeletal tension between cells (65).

Desmosomes also consist of intercellular and intracellular components. The desmosomal cadherins, desmocollin, and desmoglein interact in a heterophilic manner in the extracellular space to connect with adjacent cells. The cytoplasmic component of desmosomes consists of the proteins plakoglobin (γ -catenin), plakophilin, and desmoplakin, the latter of which connects the desmosome to intermediate filaments such as desmin (76). Desmin also links the Z-disk to costameres. Thus, desmin is uniquely situated to integrate signals from both cell–cell and cell–matrix interactions to ensure cellular integrity, force transmission, and biochemical signaling (45). Given this crucial role, it is not surprising that mutations in desmin lead to cardiomyopathy (77).

The gap junctions maintain electrical coupling of individual myocytes to form an electrical syncytium. Gap junctions ensure

Figure 3.8. Schematic representation of the major cell–cell complexes of the cardiac intercalated disc. (Reprinted from Sheikh F, Ross RS, Chen J. Cell–cell communications. *Trends Cardiovasc Med* 2010;19:182–190, with permission from Elsevier.)

the proper propagation of the electrical impulse, which triggers sequential and coordinated contraction of the cardiac myocytes. One gap junction channel consists of heptamers of the core protein connexin, of which 20 members have been identified in human (78). The main connexins expressed in the heart are connexins-40, -43, -45, and -37. In ventricular myocytes, the embryonic isoforms are connexin-40 and -43, but connexin-40 expression gradually decreases during development (79). These isoforms also exhibit distinct regional, cell type-specific and chamber-specific expression, with different isoforms present in the conduction system as compared to the ventricular myocardium (80). Six connexins combine to form one connexon that extends from the plasma membrane of one cell to dock with a connexin of an adjacent cell, creating an intercellular gap (78).

Gap junctions regulate numerous functions; the most well-known action of gap junctions is the rapid transmission of action potentials throughout the myocardium. However, connexins also allow the diffusion of metabolites and second messengers, including glucose, ATP, Ca^{2+} , cyclic nucleotides (cAMP, cGMP), and inositol phosphates (78). Connexins may also be involved in gene transcription and cell growth control through interactions with a number of cytoplasmic proteins including zona-occludens-1 (ZO-1) and actin.

Gap junction channel assembly, membrane localization, gating, and degradation are regulated by a variety of stimuli including voltage, ionic concentrations, pH, phosphorylation, and local protein interactions. For example, increases in cAMP increase the trafficking and assembly of connexins at the intercalated disk, whereas protein kinase C decreases the unitary conductance of gap junction channels (80–82).

During cardiac myocyte development and maturation, large changes in the spatiotemporal distribution of gap junctions, desmosomes, and adherens junctions occur. In the mature myocardium, all three are clustered in a bipolar pattern (perpendicular to the long axis) on the ends of the myocyte. However, during embryological development, adherens junctions are also found on the lateral membranes where they seem to be able to sense mechanical forces along the transverse axis and are thought to play an important role in myofibrillogenesis (65,83). At the perinatal stage, the adherens junctions no longer surround the entire cell, but are restricted to intercalated discs between cells. Interestingly, this polarization coincides temporally with an increase in cardiac output at birth to support the needs of the newborn, suggesting that maturation of contractility provides mechanical inputs for cadherin movement to the longitudinal border (65).

Unlike adherens junctions, gap junctions exhibit a distinct pattern of localization and are not restricted to the intercalated disc until 4 weeks after birth (84). Indeed, there is some evidence that the adherens junction complex may “prime” gap junction formation either by bringing adjacent cell membranes in close apposition or through cadherin–catenin-mediated changes in gene expression (85).

Several cardiac disorders have recently been identified in which defective electromechanical coupling between cardiac myocytes leads to degenerative cardiomyopathies characterized by contractile impairment and electrical disorders. Mutations in the desmosomal complex result in arrhythmogenic right ventricular cardiomyopathy such as those observed in Naxos disease (76,86). Mutations in proteins in the adherens junctions are associated with heart failure and dilated cardiomyopathy (75).

CORONARY VASCULATURE

The functional and metabolic demands of the developing heart require a tightly coupled growth of the coronary vasculature. As the myocardium grows and the walls thicken, passive oxygen

and nutrient diffusion is replaced by the vascular plexus that remodels to form the mature coronary circulation (87). The initiation of blood flow requires several events including the formation of the initial vascular plexus, lumen formation, initiation of heart contraction, and the entry of erythrocytes into circulation. The coordinate development of myocardium with formation of the coronary vasculature depends upon complex molecular communication between the epicardium, the subepicardial mesenchyme, and the myocardium (88). Finally, mechanical (stretch), hemodynamic (flow), and metabolic (hypoxia) signals provide additional developmental cues.

Blood vessel formation in the heart occurs by a combination of vasculogenesis and angiogenesis. Vasculogenesis is the *de novo* formation of blind-ended, tubular structures that result from the migration and incorporation of endothelial precursor cells. The origin of the endothelial cells is still somewhat controversial. Originally thought to be derived from the neural crest (89), it is now generally accepted that these cells originate from the proepicardial organ. The proepicardial organ is a transient extracardiac cell population located on the septum transversum; cells from this region migrate to the surface of the developing heart to form the epicardium. A subpopulation of these epicardium-derived progenitor cells undergoes epithelial-to-mesenchymal transition (EMT) to generate a population of cells that migrate into the underlying myocardium to give rise to endothelial cells, vascular smooth muscle cells, pericytes, and cardiac fibroblasts (87,88). Vascular smooth muscle cells of the main coronary arteries also originate from the neural crest, while coronary vein smooth muscle is derived from atrial cardiac myocytes (90,91). More recent data suggest that new coronary vessels arise from angiogenic sprouts from the sinus venosus, the major vessel that returns circulating blood to the developing heart. In this scenario, sprouting venous endothelial cells dedifferentiate as they migrate through the myocardium to form the coronary plexus and then redifferentiate and remodel into capillaries, arteries, and veins (92).

The signals that regulate coronary development are derived from both the epicardium and cardiac myocytes. Both metabolic (hypoxia) and mechanical factors stimulate growth factors that promote angiogenesis (93). The epicardium initially acts as a signaling center by secreting a variety of growth factors such as basic fibroblast growth factor (FGF), retinoic acid, TGF- β , and erythropoietin to promote cardiac myocyte proliferation and prepare the epicardium for EMT (88). EMT is promoted by growth factors secreted by both the epicardium and myocytes. Platelet-derived growth factor, FGF family members, angiopoietins, and bone morphogenetic proteins promote EMT and endothelial tube formation. Vascular endothelial growth factor (VEGF) plays multiple roles in coronary vessel development including EMT, coronary endothelial cell proliferation, migration, and tube formation and also promotes connection of the coronary plexus to the aortic root (88,89). VEGF is also the molecular link between hypoxia and angiogenesis. As the growing myocardium increases its oxygen consumption, localized hypoxia triggers hypoxia-inducible factor 1 α , which in turn drives the expression of VEGF.

Physiologic feedback between the myocardium and coronary vessels also occurs via mechanical stimuli. Mechanical stretch of the myocardium potentially induces VEGF secretion. For example, experimentally induced increases in diastolic filling (e.g., bradycardia, volume overload) cause increased myocardial angiogenesis (94) through a VEGF-dependent pathway (93,95). This effect appears to be due to increased cyclic stretch of cardiac myocytes, since cultured cells secrete VEGF in response to mechanical stretch (96).

As the heart begins to contract, the network of blood vessels initially contains only plasma followed by erythrocytes as they dislodge from blood islands (97). As blood flows through

the developing vessels, endothelial cells become exposed to shear stress, which is a function of fluid flow velocity and viscosity. Endothelial cells are equipped with a variety of “mechanosensors” that respond to shear stress and stimulate the expression of a variety of genes required for endothelial function and differentiation of arteries and veins (98). The coronary vasculature continues to grow postnatally to keep pace with increasing mass of the myocardium. In humans, the number of arterioles and capillaries steadily increases during the first postnatal year (99). Blood flow continues to drive the remodeling of the large arteries, while FGF and VEGF signaling modulate arteriolar and capillary growth (87,100).

MYOCARDIAL GROWTH AND REMODELING

Cardiac myocytes display two developmentally regulated types of growth. During fetal and early neonatal life in rats, cardiac myocytes actively proliferate (101). In the neonatal mouse heart, the ability to regenerate after injury is lost by 7 days of age, a time point that coincides with the loss of cardiac myocyte proliferative capacity (102,103). After this time point, increased cardiac myocyte growth is largely limited to hypertrophy of existing myocytes (104). Numerous signaling pathways have been shown to regulate cardiac myocyte growth. One common target of these pathways are microRNAs (miRs), small noncoding RNAs that cause coordinated posttranscriptional repression of genes by binding to distinct sequences usually located within the 3′-untranslated region of target mRNAs. It is becoming increasingly evident that miRs are important regulators of cardiac growth and function (105). For example, pioneering work by Olson’s group has identified miR-15 family members as potent inhibitors of cardiac myocyte proliferation by repressing the expression of multiple cell cycle genes (102).

TH elicits pleiotropic actions on the cardiovascular system throughout development, postnatal maturation, and adult life. In rodent cardiac myocytes, triiodothyronine (T_3) is the biologically active TH as the heart lacks tissue deiodinases required for the conversion of T_3 to thyroxine (T_4) (106). The majority of TH effects are elicited through classical nuclear TH receptors (TH- α and TH- β) that are members of a superfamily of nuclear hormone receptors that regulate gene transcription (107). TH- α receptors have distinct actions depending upon their hormone-binding state. At early embryonic stages when hormone levels are low, unliganded TH- α receptors repress expression of TH-dependent genes (108). During later stages of development, TH levels trigger the conversion of TH- α to a ligand-bound state and induce myoblasts to differentiate and express a cardiac-specific phenotype. Studies in neonatal rat myocytes indicate that TH also promotes the postnatal myosin isoform switch from the fetal β -MHC isoform to the adult α -MHC form and similar isoform shifts in troponins, MLCs, and titin (48,106,109). Additional functions of TH in cardiac innervation are discussed below.

APOPTOSIS

Cells of the heart can die by either necrosis, apoptosis (programmed cell death), or autophagy (110). Apoptosis, or programmed cell death, is a key mechanism of cardiomyocyte loss in adult heart failure. Only recently, however, has apoptosis been recognized as a key regulator of normal cardiac development (111). Both intrinsic (controlled by mitochondrial activity) and extrinsic (receptor-mediated) apoptotic pathways regulate this process (112). Several proteins in the

mitochondrial pathway include caspases (3, 6, and 9) as well as proteins encoded by the mammalian *Bcl-2* family of antiapoptotic genes (110). The extrinsic pathway involves tumor necrosis factor- α or the Fas-ligand binding to their respective cell surface receptors (113).

During development, precursor cells are recruited to the heart where they proliferate and differentiate into cardiomyocytes, fibroblasts, smooth muscle cells, as well as endocardial and endothelial cells. Proper cardiovascular remodeling during development requires strict coordination between this proliferation/differentiation and temporal activation of apoptotic events.

Myocyte proliferation and apoptosis are highest during the early stages of cardiac development. Fiorina et al. (111) showed that the number of apoptotic myocyte nuclei decreases in the third trimester (as compared to the second trimester) in human fetal heart samples. They concluded that there is a delicate balance between myocyte proliferation and death, and that this is a key mechanism in maintaining a proper heart weight/body weight ratio. Indeed, myocyte apoptosis remains relatively high up to 6 months postnatal prior to declining into adulthood.

During development, the right ventricle and left ventricle are exposed to similar volume loads. After birth, however, as the foramen ovale and ductus arteriosus close, the LV is exposed to a greater peripheral resistance than the right ventricle. Myocyte apoptosis in the right ventricle is four times higher than in the LV24 hours postnatally, and this apoptosis decreases over time (114). Overall, it is clear that apoptosis plays a key role in the transition from fetal to postnatal life; thus, it may be a target for the design of pharmacologic agents to enhance fetal heart development.

MYOCARDIAL FUNCTION

Excitation–Contraction Coupling

E–C coupling refers to the process that couples an action potential (excitation) with an intracellular Ca^{2+} transient and subsequent cross-bridge cycling and contraction. Although much attention has been paid to the mechanisms that couple surface membrane depolarization to Ca^{2+} release from the SR (Ca^{2+} -induced Ca^{2+} release), it is important to remember that changes in thick- and thin-filament expression and Ca^{2+} sensitivity also modulate the contractile response to the Ca^{2+} transient. In this section, we first provide an overview of E–C coupling in the mature myocardium, and then discuss how this process changes during development.

The “excitation” component of E–C coupling depends upon the macromolecular complex termed the Ca^{2+} release unit. Structurally, this unit is located at the T-tubule–SR junction or “triad junction” composed of a single T-tubule flanked on either side by a terminal cisternae of the SR (115). Plasma membrane L-type Ca^{2+} channels act as the voltage sensor of the complex. In response to the action potential, Ca^{2+} enters the local microenvironment through these channels to elicit Ca^{2+} release from the SR through ryanodine receptors. Ryanodine receptors bind to numerous regulatory proteins that modulate its Ca^{2+} binding (calmodulin), gating properties (FKBP 12.6), and its Ca^{2+} release (triadin, junction) or proteins that buffer SR Ca^{2+} stores (calsequestrin) (116). In this way, the ryanodine receptor is able to respond to surface depolarization in a manner that depends on the Ca^{2+} load within the SR (117). This junctional arrangement also serves as the “local control” model that describes the summation of spontaneous Ca^{2+} release or Ca^{2+} sparks from the ryanodine receptor. Ca^{2+} sparks are the fundamental units of SR Ca^{2+} release at rest (where they occur as random, stochastic events) and during E–C coupling

(116,118). During E–C coupling, thousands of Ca^{2+} sparks are synchronized by the action potential, such that the local rises in $[\text{Ca}^{2+}]$, completely overlap in time and space, making the Ca^{2+} transient appear uniform (116).

As discussed in previous sections, the “contraction” portion of E–C coupling results from Ca^{2+} binding to TnC, the binding of TnC to TnI, and the resultant dissociation of TnI from actin that increases the number of cross-bridges for force generation. The amount of force developed depends on the amplitude and duration of the Ca^{2+} transients and the Ca^{2+} sensitivity of the myofilaments. While the Ca^{2+} -induced Ca^{2+} release mechanism largely dictates the Ca^{2+} transient amplitude (with a minor component from reverse mode NCX1 exchange), SR Ca^{2+} reuptake by SERCA2a (~70%) and Ca^{2+} extrusion via the NCX1 exchanger (~30%) are the major determinants of Ca^{2+} transient duration (116).

Myofilament Ca^{2+} sensitivity is largely determined by the type of troponin isoform present. For instance, the presence of slow skeletal TnI in embryonic and early postnatal hearts is associated with an increased Ca^{2+} affinity and a decreased rate of Ca^{2+} dissociation from TnC (119). In the mature myocardium, phosphorylation of TnI by PKA (in response to β -adrenergic stimulation) decreases the Ca^{2+} affinity of the troponin complex and increases the rate of Ca^{2+} dissociation. Myofilament Ca^{2+} sensitivity is reduced by acidosis (116) and increased in response to a new class of inotropic drugs including levosimendan (120).

Changes in E–C coupling occur throughout development. Embryonic myocytes have a poorly developed T-tubule system and SR, making the fetal heart more dependent upon L-type Ca^{2+} channels and Ca^{2+} influx across the plasma membrane (121). Ryanodine receptors are expressed in neonatal myocytes, but are not involved in Ca^{2+} -induced Ca^{2+} release until the T-tubule system matures 2 weeks following birth (122). Interestingly, fetal and neonatal myocytes from early stages of cardiac development display spontaneous Ca^{2+} oscillations that are independent of membrane depolarization or Ca^{2+} influx but seem to originate from inositol trisphosphate receptor-gated channels (123). These oscillations may lead to subsarcolemmal release of Ca^{2+} from ryanodine receptors to elicit spontaneous contractions (124).

REGULATION OF E–C COUPLING

As the heart continues to mature following birth, there are considerable changes in myocardial performance. The myocardium increases contractility, diastolic relaxation, volume, and cardiac output. These postnatal changes in cardiac function reflect the developmental regulation of ion channels, receptors for neurotransmitters, and alterations in cell signaling cascades. Multiple mechanisms underlie these phenotypic changes and are classified as intrinsic (e.g., mechanical load), extrinsic (autonomic innervation, TH status), or structural (125).

Intrinsic Regulation

Changes in heart rate increase myocardial contractile force according to the cardiac force–frequency relationship, initially described by Bowditch more than a century ago (126). The force–frequency relationship is an important intrinsic regulatory mechanism of cardiac contractility and describes the relationship between force and velocity, where shortening velocity increases in a hyperbolic manner as force is reduced (127). The underlying cellular mechanisms are related to rate-dependent changes in Ca^{2+} availability (13) and myofilament Ca^{2+} sensitivity (128).

The length-dependent Ca^{2+} activation of the thin filament plays a critical role in the steep force–length relationship of cardiac muscle (Frank–Starling relationship). Quite simply, this relationship describes the observation that when cardiac myocytes are stretched longitudinally, they develop proportionally more force at a given submaximal Ca^{2+} concentration than they do at shorter myofilament lengths (129). The molecular mechanisms that underlie this intrinsic regulatory mechanism are unclear, but have been proposed to involve myofilament lattice spacing (increase in the local concentration of myosin heads due to longitudinal stretch), titin (exertion of radial force at long sarcomere lengths to pull thick and thin filaments together), or increased Ca^{2+} sensitivity of the thin filament (130). This relationship underlies the Frank–Starling mechanism that is discussed in a subsequent section of this chapter.

Sympathetic Innervation

The development of the autonomic nervous system depends upon the secretion of local trophic growth factors. The most important are the neurotrophin family members of nerve growth factor (NGF) and neurotrophins 3 and 4. Cardiac myocytes secrete NGF to promote sympathetic nerve sprouting, survival, and maintenance (131,132). Interestingly, innervation is also modulated by “neurorepellants” such as semaphorin 3a (Sema 3a) that inhibit neuronal growth. In fact, Sema 3a may be partly responsible for patterning of sympathetic innervation in an epicardial to endocardial gradient since Sem3a-deficient mice exhibit disrupted spatial patterning (133,134). These results suggest that the overall balance between NGF and Sema 3a dictates sympathetic nerve development in the heart.

The main neurotransmitters of the sympathetic nervous system are norepinephrine in presynaptic nerves and acetylcholine in postsynaptic ganglia (132). Norepinephrine stimulates both α (α_1) and β (β_1 and β_2) adrenergic receptors (ARs) in cardiac tissue. Similar to humans, the rodent heart expresses predominantly β_1 -ARs with a small fraction (15%–25%) of β_2 -receptors (135). Following β_1 -adrenergic stimulation, the G_s -dependent activation of adenylate cyclase causes an increase in cAMP and activation of PKA. PKA phosphorylates a number of proteins involved in E–C coupling that increase the peak Ca^{2+} transient amplitude (L-type Ca^{2+} channels, ryanodine receptors) and contractility coupled with an increase in the kinetics of cell shortening (TnI, phospholamban). The cAMP–PKA system also alters gene expression and cardiac growth. β_2 -Receptors elicit similar effects but display developmentally regulated responses to catecholamines. For example, β_2 -receptors have higher affinity for epinephrine than norepinephrine and neonatal receptors are more sensitive to physiologic concentrations of these neurohormones compared to β_2 -receptors in adult hearts (134).

Sympathetic innervation appears to be delayed in the rat ventricle since sympathetic nerve terminals are not observed until the third week after birth and do not fully mature to the adult pattern until 5 weeks postnatally (135), and both chronic and inotropic responses to β -adrenergic agonists are significantly weaker in 2-week-old mice compared to adult mice (136). The onset of sympathetic innervation of the mammalian ventricle is associated with functional alterations in several ion channels, including the inward Na^+ current, the L-type Ca^{2+} channel, the inward rectifier K^+ current, and delayed rectifier K^+ currents (125). These changes are likely due to a combination of altered gene expression, membrane compartmentalization, and posttranslational modifications.

In humans, parasympathetic activity in the heart is controlled by superior, inferior, and thoracic branches of the vagal nerve (132,137). The parasympathetic nervous system

uses acetylcholine as its main neurotransmitter. Acetylcholine exerts its actions predominately through M_2 cholinergic receptors although a perinatal involvement of M_1 receptors has been reported (138,139). Parasympathetic innervation of the rat heart is first detected a few days before birth, although maturation of atrial innervation is not completed until 30 to 60 days after birth (135,140). The most significant effects of parasympathetic innervation occur in the atrium, where acetylcholine interacts with M_2 receptors in the sinoatrial node and conductive tissue to increase K^+ channel activation and inhibits the pacemaker current. Both of these effects contribute to the well-known negative chronotropic actions of vagal stimulation. Inotropic effects of the parasympathetic nerves in the ventricular myocardium are primarily through antagonism of β -adrenergic stimulation largely through M_2 receptor- G_i -mediated inhibition of adenylyl cyclase.

Overall, the functional interactions of the autonomic nervous system on the neonatal heart seem to favor a net excitatory state (135). Prior to the onset of sympathetic innervation, both the β_1 -AR and β_2 -AR are functionally active and contribute to the positive chronotropic and inotropic effects of circulating catecholamines in the neonate. The cardiac ARs are responsive to adrenal catecholamines. Since β_2 -ARs have higher affinity for epinephrine versus norepinephrine, the excitatory β_2 -adrenergic signaling cascade may be more responsive to circulating rather than neuronally derived catecholamines (134). With the onset of sympathetic innervation, the resultant changes in AR density, increases in G_s/G_i ratios, and changes in ion channel expression and activation allow the maturing heart to become more responsive to norepinephrine release from local nerve terminals.

Thyroid Hormone

It is well recognized that TH regulates the expression of ARs and levels of adenylyl cyclase in the developing and adult heart. This is crucial in the neonate to ensure the transition to extrauterine life and postnatal cardiac growth and to facilitate β -adrenergic signaling prior to the arrival of sympathetic nerve terminals (141). TH also regulates the expression of several proteins involved in E-C coupling including α -MHC, titin, SERCA2a, the Na^+/K^+ -ATPase, and the NCX1 exchanger (49,142) and promotes mitochondrial biogenesis and oxidative phosphorylation (143). The observed changes in heart rate, cardiac output, and systemic vascular resistance in animal models and in patients with altered thyroid status underscore the importance of TH in normal cardiovascular function. In general, hyperthyroidism is associated with tachycardia, increased cardiac output, and systemic vasodilation. Conversely, hypothyroidism correlates with bradycardia and mild hypertension (144). Of note, plasma TH levels drop as much as 60% in infants and children undergoing cardiac bypass surgery. Promising results have been obtained in several small-scale clinical studies using T_3 therapy in infants and children undergoing cardiopulmonary bypass, showing that this therapy improves postoperative cardiac function (145,146). Early results from a larger multicenter placebo-controlled randomized trial (T_3 supplementation in infants and children undergoing cardiopulmonary bypass, TRICC) suggest that T_3 supplementation improves cardiac function in patients younger than 5 months of age and decreases the need for inotropic support (147).

Structural Changes

At the level of the cytoskeleton, changes in the relative content, posttranslational modification, arrangement, and isoform expression of various proteins can alter diastolic performance

and lead to dysfunction. Multiple studies have examined the contribution of microtubules (tubulin) (121) and intermediate filaments (desmin) (148) to relaxation, where aberrant changes can lead to increased stiffness. Early work by Tagawa et al. (149) examined cardiomyocytes using a method of single-cell mechanical loading of myocytes. They found that cytoskeletal stiffness and viscosity increased significantly in cats exposed to pressure overload hypertrophy. This apparent stiffness and viscosity was reversed and cardiomyocyte function was restored upon the addition of the microtubule depolymerization drug colchicine.

The intermediate filament desmin reinforces myocyte sarcomeres and contributes to the overall diastolic tone. Dynamic increases in desmin have been noted in models of diastolic dysfunction including microembolization (leading to global ischemia) in sheep (150) and ventricular septal defects in pigs (151). In addition to changes in relative abundance, reports have suggested that posttranslational modification (nitration) of this protein is associated with oxidative stress-induced systolic and diastolic dysfunction (152).

Sarcomeric titin is attributed with providing much of the passive elastic properties of the cardiac muscle. Over the normal operating range of sarcomere lengths ($<2.2 \mu m$), titin contributes to sarcomeric stiffness more than the microfilaments and intermediate filaments that provide $<10\%$ of the elastic force (153). Shifts in the relative content of the larger more compliant N2BA isoform versus the smaller and stiffer N2B isoform are implicated in multiple forms of diastolic dysfunction, including aortic stenosis (154), hypothyroidism-induced LV dysfunction (53), and pacing-induced cardiac failure (155,156).

In summary, the combination of neurohormonal programming, autonomic innervation, and mechanical forces coordinate postnatal cardiac growth and E-C coupling in order to increase cardiac output to meet the metabolic demands of the rapidly growing organism.

LV CHAMBER FUNCTION

Systole

Cardiac output is tightly matched to meet the metabolic needs of the body via feedback mechanisms that prevent a mismatch between supply and demand. Systole refers to the process of force generation and shortening in the LV, where blood is ejected into the systemic circulation, a process that is initiated by the coordinated propagation of the action potential. Systolic ejection is regulated by three phenomena: end-diastolic fiber length (the Frank-Starling mechanism), afterload, and intrinsic myocardial contractility.

Pioneering work in the late 19th century by Otto Frank (157) and in the early 20th century by Ernest Starling and colleagues (158,159) determined that the cardiac ejection volume (stroke volume) of the heart increases in response to increased preload (diastolic filling of the heart). As described earlier, this response is mediated by an increased responsiveness of the myofilament apparatus to Ca^{2+} at longer sarcomere lengths (160). The Frank-Starling mechanism ensures that over a physiologic range, on average, the same amount of blood is pumped out of the left and right ventricles.

Afterload (also referred to as aortic resistance/impedance) is the work that the LV must overcome to eject a given volume of blood (stroke volume). Afterload has an inverse relationship with stroke volume. This relationship is most notably evident in cases of arterial hypertension, where the increased afterload results in a decreased stroke volume in the LV. To alleviate the effects of afterload, it is common to administer vasodilators in order to increase forward ejection fraction.

Figure 3.9. A: Schematic of a PV loop generated by a normal human LV. The loop is constrained by the end-diastolic pressure–volume relationship (EDPVR) and by the end-systolic pressure–volume relationship (ESPVR). See text for further details. B: A series of pressure–volume loops were obtained in a rat heart by occluding the inferior vena cava, in order to obtain load-independent measures of contractility (slope of ESPVR or E_{es}) and LV compliance (slope of EDPVR).

Diastolic Relaxation

Diastole occurs at the beginning of isovolumic relaxation (see Fig. 3.9) and ends with mitral valve closure. This allows ventricular filling and involves the interaction between active, energy-dependent processes (myocardial relaxation) that primarily influence early ventricular filling and passive processes, such as loading conditions and myocardial compliance. Active LV relaxation is dependent upon the rate of myocyte $SR\ Ca^{2+}$ reuptake by SERCA2a and by titin. The rate of global LV myocardial relaxation is reflected by the monoexponential course of LV pressure fall. Tau is a widely accepted invasive measure of the rate of LV relaxation.

The role of the ECM is also paramount in regulating diastolic function in the context of normal function and disease. As discussed in preceding sections, the ECM forms the scaffold that tethers and signals to the cardiac myocyte, and changes in the makeup or content of the ECM can be detrimental to diastolic filling. The ECM forms a scaffold that is composed primarily of collagen fibers, which allow for the transmission of mechanical force generated by cardiomyocytes. A multitude of evidence reveals that collagen can also regulate myocardial stiffness and diastolic and systolic function via contribution from changes in collagen volume fraction, collagen isoform composition (collagen I/III ratio), and collagen cross-linking contribution (161).

PRESSURE–VOLUME LOOP ANALYSES OF CONTRACTILE FUNCTION

Although currently limited in clinical use, pressure–volume (PV) analysis is potentially a powerful tool that could be applied for use in assessment of pediatric diseases. The procedure

requires the introduction of a catheter (commonly through the femoral artery) into the LV that reads simultaneous pressure and volume during the cardiac cycle. These values are then displayed by plotting instantaneous ventricular pressure versus volume. A typical trace is shown in Figure 3.9A. At point *a*, filling of the LV chamber begins during diastole after the mitral valve opens and continues to point *b*. The pressure does not change substantially due to progressive LV relaxation and passive compliance. The small increase in pressure just prior to point *b* reflects the contribution of atrial contraction to LV filling. With the onset of LV isovolumetric contraction (line *b–c*), the pressure rises steeply but volume does not change since both the mitral and aortic valves are closed. When the rise in ventricular pressure exceeds the diastolic pressure in the aorta (point *c*), the aortic valve opens, and during the first phase of ejection (rapid ejection, line *c–d*), the large reduction in volume is associated with increased LV pressure. This is followed by a period of reduced ejection and a decrease in LV pressure. This phase corresponds to the onset of cardiac myocyte relaxation. Once the pressure falls below systolic aortic pressure, the aortic valve closes (point *e*). As the ventricle continues to relax, the pressure decreases but volume remains constant since the mitral valve has not yet opened. This phase is referred to as isovolumetric relaxation. When the LV pressure falls below that in the left atrium, the mitral valve opens again and the cycle repeats.

This method can be used to determine load-dependent indices of systolic function, including, but not limited to, the following systolic parameters: ejection fraction, the first derivative ($+dp/dt$) of the rate of developed pressure, stroke work (area within the PV loop), and stroke volume. Load-dependent parameters used for analysis of diastolic function include end-diastolic pressure, tau, and $-dp/dt$. Furthermore, load-independent function can be evaluated using PV analysis, which is accomplished by occluding either the inferior vena cava or the descending thoracic aorta using a balloon

catheter (Fig. 3. 9B). This generates a series of PV curves that allow for the measurement of indices of load-independent contractility including end-systolic elastance (Ees; slope of the end-systolic PV relationship curve) and preload-recrutable stroke work. The relationship generated from the end-systolic elastance has been shown to have a high correlation with the Frank-Starling relationship of the heart, with steeper slopes indicating increased contractility. Although this systolic relationship is generally considered nonlinear, a line can be fit to this curve as long as the volume axis intercept is also examined. For instance, a shift in the Ees line to the left (such as that occurring following administration of a β -adrenergic agonist) accompanied by little change in slope would indicate an increase in contractility since there is increased end-systolic pressure generation at a common volume. Afterload can also be assessed using PV analysis by comparing the stroke volume of the ventricular contraction to the end-systolic pressure required to eject (higher end-systolic pressure with common stroke volumes would indicate a higher afterload).

Furthermore, left ventricular chamber stiffness can be assessed using this series of PV curves. This relationship, which is based on the points in the end-diastolic pressure-volume relationship (EDPVR), provides an accurate assessment of compliance, with shift to the right and down indicating increased compliance. Several extrinsic and intrinsic factors determine these end-diastolic properties. Extrinsic factors are pericardial restraint and ventricular interaction. Intrinsic factors include myocardial stiffness (cardiomyocytes and ECM), myocardial tone, chamber geometry, and wall thickness (162).

EMERGING CONCEPTS AND CONCLUSION

Research into the developing myocardium is still in its infancy, with numerous studies emerging within the last 5 years. Recently, the role of cardiac-resident stem cells in the prenatal and postnatal heart has become a popular area of study, with suggestions that the heart can regulate its own internal environment by recruitment of stem cells to areas within the heart for growth and maturation (163–166). Gene therapy is also increasingly popular in the developing heart, with studies suggesting that genes can be delivered to the myocardium to regulate expression and control growth (167–169). These areas of research will likely continue to increase our understanding of the developing heart and how it functions, and assist in developing novel therapeutic approaches for the treatment of pediatric cardiovascular diseases.

David F. Teitel ■ Steven C. Cassidy ■ Jeffrey R. Fineman

The circulation can be divided into its central components, consisting of the central arteries, veins, and, in the fetus, central shunts, and its peripheral components, consisting of the various regional vascular beds. Each component undergoes significant changes throughout fetal and postnatal development. General physiologic principles of blood flow will be presented first, followed by specific considerations pertaining to blood flow through the central and peripheral circulations, including developmental changes.

PHYSIOLOGY

General Physiology

Physical Determinants of Flow

Physical factors that regulate flow through a vascular bed exert their effects through the hydraulic equivalent of Ohm's law (resistance equation) and the Poiseuille-Hagen relationship. In vascular terms, Ohm's law states that resistance to flow between two points along a tube equals the pressure difference between the two points divided by flow. With vascular resistance R and blood flow Q , the mean pressure decrease that occurs from the artery (P_a) to the vein (P_v) can be derived from the formula

$$R = \frac{P_a - P_v}{Q}$$

To assess changes in arterial blood pressure in response to changes in flow and resistance, the formula can be rearranged as

$$P_a = Q \times R + P_v$$

Thus, elevation of arterial blood pressure may occur in response to an increase in either vascular resistance or blood flow. However, these factors are not independent; for example, arterial blood pressure may remain constant when blood flow increases if the increased flow causes vascular resistance to decrease. This can occur by the recruitment of partially or fully closed arterioles—if the product $Q \times R$ does not increase, arterial pressure does not.

Further factors that affect the resistance to flow can be approximated by the Poiseuille-Hagen relationship, which describes the relationship of pressure and flow of a Newtonian fluid flowing through a straight, round glass tube:

$$R = \frac{8l\eta}{\pi r^4}$$

where l is the length of the tube, r is its internal radius, and η is the fluid viscosity. Blood is not Newtonian. The walls of the small arteries are not smooth, and the arteries branch, curve, and taper. Blood flow is pulsatile, so that additional energy (and therefore a higher pressure) is needed to overcome inertia and to accelerate the blood at each ejection. Because of short distances between arterial branch points, laminar flow is unlikely in peripheral vascular beds, and viscous pressure losses are greater than in a classical physical model. Arteries are also distensible, and the continuously changing transvascular pressure alters their radii. Lastly, vascular beds are composed of many blood vessels in parallel. These vessels are not all open all the time, and they may differ in radii in different zones. For all of these reasons, pressure–flow relationships are not linear.

Despite these complicating factors, the general principles of changes in physical factors such as viscosity and radius apply. Vascular resistance is directly related to the viscosity of blood perfusing the vascular bed and inversely related to its cross-sectional area (r^4). Increasing viscosity or decreasing vessel radius therefore leads to an elevation of both arterial pressure and vascular resistance when blood flow remains constant (1).

CENTRAL CIRCULATION

The central circulation is structured very differently in the fetus, primarily to accommodate the different site of oxygen uptake. In the postnatal state, oxygen uptake occurs in the pulmonary vascular bed, which is perfused independently by the right ventricle; the left ventricle separately supplies the regional systemic vascular beds with fully oxygenated blood. In the fetal state, oxygen uptake occurs in the placenta, which is perfused in parallel with the systemic vascular beds. To deliver relatively highly oxygenated blood to the metabolically active tissues (such as the heart and brain) and to deliver less oxygenated blood to the placenta for oxygen uptake, central shunts and preferential blood flow patterns exist. Shunts are present in the venous system (ductus venosus), the heart (foramen ovale), and the arterial system (ductus arteriosus) and are remarkably efficient at achieving this goal. At birth, these shunts are abolished over a very short period of time, and the mature postnatal central circulation is established within the first few days of life.

Fetal Circulation

The presence of central shunts allows the fetal circulation to be remarkably efficient at distributing oxygen and substrate. Figure 4.1 demonstrates that the fetal ventricles primarily perform their postnatal functions: The fetal right

Figure 4.1. Preferential pattern of ventricular output. The left ventricle (LV) directs most of its highly saturated blood (red arrow) via the ascending aorta (AAo) to the highly metabolic heart and upper body. The right ventricle (RV) primarily ejects less oxygenated blood (purple arrow) via the main pulmonary artery (MPA) primarily down the ductus arteriosus (PDA) and via the descending aorta (DAo) to the placenta for oxygen uptake. RA, right atrium; LA, left atrium.

ventricle supplies most of its blood via the ductus arteriosus and descending aorta to the placenta for oxygen uptake, and the left ventricle supplies most of its blood via the ascending aorta to the heart and brain for oxygen delivery. For the central venous circulation to facilitate the efficient performance of these tasks, the least saturated venous blood should be directed to the right ventricle and the most saturated should be directed to the left. To appreciate how this is achieved, it is best to consider the five components of the central venous circulation in turn. These components are the venous returns from the upper body, the myocardium, the lungs, the lower body, and the placenta.

The least saturated blood returns from the upper body, via the superior vena cava, and from the myocardium, via the coronary sinus. This blood is directed appropriately, through the tricuspid valve to the right ventricle. The leftward and superior course of the eustachian valve directs >95% of the blood flowing caudally from the superior vena cava away from the foramen ovale and toward the tricuspid valve. In addition, the location of the coronary sinus caudad to the foramen ovale causes venous blood from the myocardium to flow through the tricuspid valve to the right ventricle (Fig. 4.1). Blood returning from the lungs has an intermediate saturation, but by the nature of the normal drainage of the pulmonary veins to the left atrium, preferential flow to the right ventricle is not possible. However, pulmonary blood flow is a relatively small portion of combined venous return. It represents no more than 8% of combined ventricular output in the sheep fetus (2), and about twice that in the human, at most being 25% (3), so that it does not have a significant effect on oxygen delivery.

Inferior vena caval return comes from the remaining two sources, the lower body and the placenta. Most lower body flow, except that from the liver, ascends the distal inferior vena cava. This stream of relatively desaturated blood enters the lateral margin of the right atrium and is directed primarily through the tricuspid valve. Placental (umbilical venous) and liver venous return is more complicated (Fig. 4.2). Under

normal conditions in the fetal sheep, about 55% of the highly saturated umbilical venous return ascends via the ductus venosus to the inferior vena cava–right atrium junction, where it preferentially crosses the foramen ovale (2). Slightly less than half of the remaining umbilical venous return enters the left lobe of the liver, from which it reaches the left hepatic vein (4). The left hepatic vein joins the ductus venosus near the inferior vena cava, so that this highly saturated blood is also directed toward the foramen ovale. The limbus of the foramen ovale helps to direct this blood into the left atrium. The remainder of the umbilical venous blood, along with >95% of the poorly saturated portal venous blood, is directed to the right lobe of the liver. From the right lobe, this much less saturated blood enters the right hepatic vein and tends to stream with the blood of the distal inferior vena cava to the tricuspid valve. The hepatic artery, which carries blood that is moderately well saturated, constitutes <10% of hepatic blood flow in the fetus, so it does not significantly contribute to oxygen supply. Hepatic arterial blood is distributed to both lobes of the liver, with the right lobe receiving somewhat more (4).

Thus, preferential streaming patterns among the different sources of venous return allow most of the poorly saturated blood from the upper body, myocardium, and lower body to reach the right ventricle, and the more highly saturated umbilical venous return to reach the left ventricle. Although the separation of fetal venous return and ventricular output according to its level of blood oxygenation is not as efficient as the postnatal separation, it is quite remarkable in its ability to allow the right and left ventricles to perform their normal postnatal functions of delivery of blood for oxygen uptake and oxygen supply, respectively.

Postnatal Circulation

The changes in the central circulation at birth are primarily caused by external events rather than by primary changes in

Figure 4.2. Preferential pattern of venous return to the right (RV) and left (LV) ventricles. More highly saturated blood (red arrow) from the umbilical vein (UV) passes via the ductus venosus (DV) and left hepatic vein (LHV) to the left atrium (LA) and LV. Less saturated blood (blue arrows) from the lower body via the inferior vena cava (IVC, not shown), from the main and right portal veins (MPV and RPV) via the right hepatic vein (RHV), from the coronary sinus (CS), and from the superior vena cava (SVC) passes to the right atrium (RA) and RV.

the circulation itself. Most important of these external events are the rapid and large decrease in pulmonary vascular resistance and the disruption of the umbilical-placental circulation. The various mechanisms responsible for the decrease in pulmonary vascular resistance are discussed later in this chapter. This decrease has profound effects on the central shunts in the systemic circulation. Abruptly at birth, the ductus arteriosus changes from a right-to-left conduit of blood to the descending aorta, to a left-to-right conduit of blood to the lungs, until it closes in the first hours or days of life. This shunt may be prolonged in the premature infant, causing a steal of blood from the regional systemic vascular beds of greatest resistance. The physiologic basis of normal closure of the ductus arteriosus and problems associated with delayed closure are discussed elsewhere (see Chapter 19).

As previously mentioned, the ductus venosus carries umbilical venous return primarily to the left heart. Although the amount of umbilical venous blood that enters the ductus venosus is variable and is greatly affected by stresses such as hypoxemia, changes in flow do not appear to be caused by active vasoconstriction of the ductus venosus, but rather, occur passively in accordance with changes in umbilical blood flow. At birth, the umbilical-placental circulation is abolished, causing a marked reduction in ductus venosus flow and in flow to the left lobe of the liver. However, portal venous flow through the ductus venosus increases from <5% to >50% by 1 hour of age so that, despite an increase in portal venous flow at birth, blood flow to the liver itself actually decreases substantially (5). This shunt of portal venous blood through the ductus

venosus is transient, generally lasting for 1 day to 2 weeks. The functional closure of the ductus venosus is probably a passive phenomenon, although it has been demonstrated that the isolated ductus venosus can respond to adrenergic stimulation and prostanoids. In the intact newborn lamb, it can dilate in response to prostaglandin E_1 (6). Thus, its closure may be partly induced by the same hormonal changes that are implicated in the closure of the ductus arteriosus.

Although vasoactive processes are involved in the closure of the ductus arteriosus, and may be involved in closure of the ductus venosus, closure of the foramen ovale at birth is entirely passive, secondary to alterations in the relative return of blood to the right and left atria. Prior to birth, direct left atrial return via the pulmonary veins is only modest, $\leq 25\%$ of combined venous return. Thus, the pressure gradient from the right atrium to the left maintains a large flow of blood through the foramen ovale, which appears as a wind sock bulging into the left atrium. With the onset of oxygen ventilation, the proportion of combined venous return that directly enters the left atrium via the pulmonary veins increases dramatically, to >50% (2). This is because of the marked increase in pulmonary blood flow, which includes a transient left-to-right shunt through the ductus arteriosus. Left atrial pressure thus exceeds right, and the redundant flap of tissue of the foramen ovale that previously bowed into the left atrium is now pressed against the septum. Small left-to-right shunts may be visualized in the newborn by color Doppler ultrasonography, but these shunts are not hemodynamically significant. Although patency of the foramen ovale may be present for several years, shunts of any significance occur only when the primum septum is deficient, thus forming a secundum atrial septal defect (see Chapter 28).

PULMONARY CIRCULATION

Although considerable information is available regarding the complex physiologic regulation of pulmonary vascular resistance, the exact mechanisms involved in intrinsic relaxation and constriction of the pulmonary vascular smooth muscle are not completely understood. The important functional role of the vascular endothelium and its interactions with smooth muscle are only now being brought to light. The pulmonary vessels not only produce many vasoactive substances, but also actively metabolize many. Changes in pulmonary vascular resistance can occur at different levels within the circulation, and vasoactive substances and their properties may change during passage through the pulmonary vascular bed. Accurate physiologic characterization of the pulmonary circulation varies with the gender, age, and species of the model used and the exact compartment of the pulmonary circulation evaluated. Whether all the principles that apply to systemic vascular smooth muscle also apply to the pulmonary circulation is not yet clear. However, the final common pathway by which vascular smooth muscle constricts is by Ca^{2+} -mediated stimulation of excitation-contraction coupling. Relaxation occurs mainly either through a cyclic guanosine monophosphate (cGMP)- or cyclic adenosine monophosphate (cAMP)-mediated mechanism. Many interacting factors are responsible for the physiologic and physical control of pulmonary vascular resistance in the fetus and for its normal decrease after birth.

MORPHOLOGIC DEVELOPMENT

The stage of morphologic development of the pulmonary circulation affects the vascular responses in the perinatal period.

In the fetus and newborn, all small pulmonary arteries have a thicker medial smooth muscle layer in relation to diameter than similar arteries in adults. This increased muscularity is partly responsible for the increased vasoreactivity and pulmonary vascular resistance in the fetus, particularly near term. In fetal lamb lungs, when perfusion is fixed at pressures equivalent to those *in utero*, the muscle is most prominent in the smallest resistance arteries (identified as fifth- and sixth-generation arteries; external diameter 20 to 50 μm), and over the latter half of gestation, the thickness remains constant in relation to diameter.

Similar observations using slightly different techniques have been made in human lungs. In these, the small pulmonary arteries are identified by their relationship to airways. Preacinar arteries course proximal to or along with terminal bronchioli; intra-acinar arteries course along with respiratory bronchioli or alveolar ducts, or within the alveolar walls. In arteries traced along the airways toward the alveoli, a point is reached at which the completely encircling medial smooth muscle coat gives way to a region of incomplete muscularization. In these partially muscularized arteries, the smooth muscle is arranged in a spiral or helix. The muscle then disappears from the arteries that are still larger than capillaries (nonmuscularized small pulmonary arteries). In these arteries, an incomplete pericyte layer is found within the endothelial basement membrane; in the nonmuscular portions of the partially muscular small pulmonary arteries are intermediate cells (i.e., cells intermediate in position and structure between pericytes and mature smooth muscle cells). These cells are precursor smooth muscle cells. Under certain conditions, such as hypoxia, they may rapidly differentiate into mature smooth muscle cells.

In the near-term fetus, only about half the precapillary arteries (those associated with respiratory bronchioli) are muscularized or partially muscularized, and the alveoli are free of muscular arteries. In the first 4 to 6 weeks after birth, there is progressive involution of the circumferential medial smooth muscle with overall reduction in medial muscular thickness of the walls of the small pulmonary arteries. In adults, circumferential muscularization extends peripherally along the intraacinar arteries so that most are completely muscularized, although with only a very thin layer of smooth muscle; this adult-like pattern is reached at about puberty.

During fetal growth, the number of small arteries increases greatly. In humans the main preacinar pulmonary arterial branches that accompany the larger airways are developed by 16 weeks' gestation. However, the intraacinar circulation follows alveolar development late in gestation and after birth, and arteries multiply as alveoli develop, a process generally complete by about 10 years of age (7,8).

There is an important new appreciation of the co-development and regulation of vascular and alveolar growth. These interactions likely have significant clinical implications particularly in conditions of lung hypoplasia, where vascular hypoplasia is emerging as an important clinical problem (9).

Fetal Circulation

In the fetus, gas exchange occurs in the placenta and pulmonary blood flow is low, supplying nutritional requirements for lung growth and allowing the lung to serve a metabolic or paraendocrine function. Pulmonary blood flow in near-term fetal lambs (term being 145 days of gestation) is about 100 mL/100 g wet lung weight (8% to 10% of combined ventricular output). Pulmonary blood flow is low despite the dominance of the right ventricle, which in the fetus ejects 55% to 60% of total cardiac output. Most of the right ventricular output is diverted away from the lungs through the widely patent

ductus arteriosus to the descending thoracic aorta and the placenta for oxygenation (Fig. 4.1). In young fetuses at about 0.5 gestation, 3% to 4% of total cardiac output perfuses the lungs; this increases to about 6% at 0.8 gestation, corresponding temporally with the onset of the release of surface active material into lung fluid. There is a further progressive slow increase thereafter to 8% to 10% near term. Fetal pulmonary arterial mean blood pressure increases progressively with gestation and at term is about 50 mm Hg, exceeding mean aortic blood pressure by 1 to 2 mm Hg. Total pulmonary vascular resistance early in gestation is extremely high relative to that in the infant or adult, probably owing to the small number of small arteries present. Total pulmonary vascular resistance decreases progressively over the last half of gestation, with growth of new arteries and an overall increase in cross section. However, when lung growth is accounted for, the pulmonary vascular resistance per unit of lung tends to increase over late gestation (10,11).

Transitional Circulation

At birth, with initiation of pulmonary ventilation, pulmonary vascular resistance decreases rapidly and is associated with an eightfold to tenfold increase in pulmonary blood flow. In normal full-term lambs, pulmonary arterial blood pressure decreases to near-adult levels within 2 to 3 hours. In humans this takes longer, and by 24 hours of age, mean pulmonary arterial blood pressure may be half systemic. After the initial rapid decrease in pulmonary vascular resistance and pulmonary arterial blood pressure, there is a slow, progressive decrease, with adult levels reached after 2 to 6 weeks (Fig. 4.3). This is due to vascular remodeling, muscular involution, and rheologic changes.

Physiologic Regulation of Pulmonary Vascular Resistance

As previously discussed, pulmonary vascular resistance in the fetal lung is initially high and decreases slightly throughout the final third of gestation. Many factors, including mechanical effects, state of oxygenation, and the production of vasoactive substances, regulate the tone of the fetal pulmonary circulation. The most prominent factor associated with high fetal pulmonary vascular resistance is the normally low blood and alveolar O_2 tension. In the fetal lamb, resistance is further increased by hypoxemia and lowered by increasing oxygen tension, a vasoactive response that becomes active in the latter third of gestation. The exact mechanism and site of hypoxic pulmonary vasoconstriction in the fetal pulmonary circulation remains unclear. In isolated fetal pulmonary arteries, oxygen modulates the production of both prostacyclin and endothelium-derived nitric oxide (EDNO): two potent vasoactive substances that may in part underlie the responses of the developing pulmonary circulation to changes in oxygenation. In addition to the low oxygen environment, many substances constrict the pulmonary circulation of the fetus, such as α agonists, thromboxane, and the leukotrienes. However, their role, if any, in the maintenance of the high fetal pulmonary vascular resistance does not appear prominent (12–14). In addition to the production of vasoconstrictors, the fetal pulmonary circulation actively and continuously produces vasodilating substances that modulate the degree of vasoconstriction under normal conditions and may play a more active role during periods of fetal stress. These substances are mainly endothelially derived and include EDNO and prostacyclin (PGI_2). EDNO is synthesized by the oxidation of the guanidino nitrogen moiety of L-arginine.

Figure 4.3. The changes in pulmonary arterial pressure, blood flow, and vascular resistance that occur around birth. (Data from Morin FC III, Egan E. Pulmonary hemodynamics in fetal lambs during development at normal and increased oxygen tension. *J Appl Physiol* 1992;73:213–218; and Soifer SJ, Morin FC III, Kaslow DC, et al. The developmental effects of prostaglandin D₂ on the pulmonary and systemic circulation in the newborn lamb. *J Dev Physiol* 1983;5:237–250.)

After certain stimuli, such as shear stress or the receptor binding of specific vasodilators (endothelium-dependent vasodilators), nitric oxide (NO) is synthesized by the activation of NO synthase, and NO is then released from the endothelial cells. Once released from endothelial cells, NO diffuses into vascular smooth muscle cells and activates soluble guanylate cyclase, the enzyme that catalyzes the production of guanosine-3'-5'-cyclic monophosphate (cGMP) from guanosine-5'-triphosphate. Activation of guanylate cyclase increases the concentrations of cGMP, thus initiating a cascade that results in smooth muscle relaxation (Fig. 4.4). Endothelial production of NO and cGMP has been demonstrated in the fetal, newborn, and adult pulmonary vasculature. In fetal lambs, inhibition of EDNO synthesis produces marked increases in resting fetal pulmonary vascular resistance and inhibits the oxygen-induced decrease in pulmonary vascular resistance. In addition, studies of intrapulmonary arteries and isolated lung preparations of the sheep show maturational increases in NO-mediated relaxation during the late fetal and early postnatal period. These data suggest that basal EDNO production is an important mediator of both normal fetal pulmonary vascular tone and the dramatic decrease in resistance that occurs with the onset of oxygen ventilation at birth (15–17). Prostacyclin is synthesized primarily in vascular endothelial cells and produces vasodilation by activating adenylate cyclase via receptor G protein-coupled mechanisms. Activation of adenylate cyclase results in increased adenosine 3',5'-cyclic monophosphate (cAMP) concentrations, thus initiating a cascade that results in smooth muscle relaxation. Although there is a maturational increase in PGI₂ production throughout gestation, basal PGI₂ activity does not appear to be an important mediator of resting fetal pulmonary vascular tone. Interestingly, endothelin-1 (ET-1) is another potent endothelially derived vasoactive factor with both vasodilating and vasoconstricting effects. The hemodynamic effects of ET-1 are mediated by at least two distinct receptor populations, ET_A and ET_B. ET_A receptors are located on vascular smooth muscle cells and are likely responsible for the vasoconstricting effects of ET-1, whereas most ET_B receptors are located on endothelial cells and are likely responsible for the vasodilating effects of ET-1. The predominant effect of exogenous ET-1 in the fetal and newborn pulmonary circulation is vasodilation, mediated via ET_B receptor activation and EDNO release. However, the predominant effect in the juvenile and adult pulmonary circulation is vasoconstriction, mediated via ET_A receptor activation. In fetal lambs, selective ET_A receptor blockade produces small

Figure 4.4. Schematic of the nitric oxide (NO)-cGMP pathway. Endogenous NO is produced from L-arginine within the pulmonary vascular endothelial cell. After diffusing into the smooth muscle cell, NO activates guanylate cyclase. The resulting increase in cGMP concentration induces relaxation. Exogenous NO (inhaled NO) diffuses from the airspace into the smooth muscle cell, where it activates guanylate cyclase. When it diffuses into the bloodstream, NO binds to hemoglobin to form methemoglobin and is inactivated.

decreases in resting fetal pulmonary resistance, suggesting a potential, minor role for basal ET-1-induced vasoconstriction in maintaining the high fetal pulmonary vascular resistance. Although plasma concentrations of ET-1 are increased at birth, animal data suggest that basal ET-1 activity does not play an important role in mediating the transitional or resting postnatal pulmonary circulation (18).

The decrease in pulmonary vascular resistance and increase in pulmonary blood flow with ventilation were, for a long time, thought mainly to be due to the increase in alveolar oxygen tension with a contribution from the physical expansion of the lung. The role of oxygen was supported by increased pulmonary flow with hyperbaric oxygenation without ventilation. Some pulmonary vasodilation occurs by inflating the lungs with a low oxygen-containing gas mixture that does not change arterial blood gas composition. Adding oxygen completes the vasodilator process. The exact mechanisms of oxygen-induced pulmonary vasodilation during the transitional circulation remain unclear. The increase in alveolar or arterial oxygen tension may decrease pulmonary vascular resistance either directly via potassium channel activation or indirectly by stimulating the production of vasodilator substances such as PGI₂, bradykinin, adenosine, adenosine-5'-triphosphate, or EDNO. Inflating the lung with a low-oxygen gas mixture may lower pulmonary vascular resistance by either physical or chemical mechanisms. One mechanism operates through changes in alveolar surface tension. Another more important mechanism is the production and release of prostaglandins (predominantly PGI₂), which occurs either with mechanical stimulation of the lung or with rhythmic lung expansion (19,20).

Exogenous prostaglandins, particularly PGI₂, lower pulmonary vascular resistance in the fetus. In addition, inhibiting prostaglandin production with indomethacin before fetal lung ventilation attenuates the subsequent decrease in pulmonary vascular resistance that occurs after the initial (~first 30 seconds) rapid decrease in resistance. However, exogenous PGE₂ and PGI₂ also produce systemic vasodilation in fetal animals, whereas systemic vascular resistance normally rises when ventilation begins. Therefore, other prostaglandins, such as PGD₂, could be involved in pulmonary vasodilation. In newborn animals, PGD₂ produces greater pulmonary than systemic vasodilation; this differential effect is lost by about 12 to 15 days of age, when PGD₂ produces pulmonary vasoconstriction. This is similar to the effects of histamine, a modest pulmonary vasodilator in the immediate perinatal period and later a pulmonary vasoconstrictor. Both PGD₂ and histamine are released from mast cells, which increase in number in the lungs over the last portion of gestation; after birth, they decrease markedly. Thus, the stimulus of lung expansion may cause mast cells to degranulate, release PGD₂ and histamine, and contribute to the initial postnatal pulmonary vasodilation.

Adenosine and adenosine triphosphate also produce potent pulmonary vasodilation in the fetus via purine receptor activation. Animal studies suggest that their release at birth has a significant role in oxygen-induced pulmonary vasodilation. Bradykinin, another vasoactive agent, also is a potent pulmonary vasodilator in the fetus. However, bradykinin receptor blockade does not attenuate the decrease in pulmonary vascular resistance at birth in the lamb, casting doubt over the importance of bradykinin in postnatal pulmonary vasodilation.

Endothelium-derived NO has been implicated as an important mediator of the decrease in pulmonary vascular resistance at birth associated with increased oxygenation. For example, inhibition of NO synthesis attenuates the increase in pulmonary blood flow owing to oxygenation of fetal lambs induced by either maternal hyperbaric oxygen exposure or *in utero* ventilation with oxygen. *In utero* ventilation

without changing fetal blood gases increases epithelial nitric oxide synthase (eNOS) gene expression in lung parenchyma of fetal lambs; this is further increased by ventilation with 100% oxygen. *In vitro* data reveal a maturational increase in EDNO production from late gestation to the early postnatal period that is modulated, in part, by oxygen. Moreover, both acute and chronic inhibition of NO synthesis prior to delivery significantly attenuate the normal increase in pulmonary blood flow at birth. These data suggest an important role for EDNO activity during the transitional circulation. However, the immediate decrease in pulmonary vascular resistance minutes after birth is not attenuated by NO inhibition. Therefore, there appear to be at least two components to the decrease in pulmonary vascular resistance with the initiation of ventilation and oxygenation. First, pulmonary vasodilation is caused by physical expansion of the lung and the production of prostaglandins (PGI₂ and PGD₂). This probably is independent of fetal oxygenation and results in an increase in pulmonary blood flow and decrease in pulmonary vascular resistance. Second, there is a further maximal pulmonary vasodilation associated with fetal oxygenation that is independent of prostaglandin production; it is most likely caused by the synthesis of EDNO, although the exact stimuli for EDNO production have not yet been defined. Both components are necessary for the successful transition to extrauterine life.

Control of the perinatal pulmonary circulation, therefore, probably reflects a balance between factors producing active pulmonary vasoconstriction (leukotrienes, low oxygen, and possibly even ET-1 acting through the ET_A receptor) and those leading to pulmonary vasodilation (EDNO, ET-1 acting through the ET_B receptor, bradykinin, and prostaglandins). The dramatic increase in pulmonary blood flow after birth most likely reflects a shift from active pulmonary vasoconstriction to active pulmonary vasodilation. It is possible that arachidonic acid metabolism shifts from lipoxygenase products in the fetus toward cyclo-oxygenase products owing either to mechanical stimulation with lung expansion or to the higher oxygen environment after birth.

After the immediate postnatal period, the more important factors affecting pulmonary vascular tone and resistance are oxygen concentration, pH, the basal production of EDNO, the effects of alveolar distention, and perhaps the production of other vasoactive agents such as histamine, 5-hydroxytryptamine, ET-1, prostanoids, thromboxanes, and the leukotrienes. The interaction of oxygen and pH is particularly important. Decreasing oxygen tension and decreases in pH elicit vasoconstriction of the resting pulmonary circulation. The mechanisms of acute hypoxic pulmonary vasoconstriction remain unclear and are the subject of several extensive reviews. Acidosis potentiates hypoxic pulmonary vasoconstriction, and alkalosis reduces it. The exact mechanism of pH-mediated pulmonary vasoactive responses also remains incompletely understood, but appears to be independent of pCO₂ (7,17). More recent data suggest that potassium channels play an important role in mediating these responses (21,22).

POSTNATAL PERIPHERAL CIRCULATION

The peripheral circulation is composed of a wide variety of regional vascular beds, each with its own characteristics. Several mechanisms regulate blood flow to these beds and affect each bed to a varying degree. These include central regulatory mechanisms such as neural activity and hormonal levels, and local mechanisms including local metabolic and pressure-flow (autoregulation) control. These mechanisms are first

presented, and then the individual vascular beds are discussed, according to their primary control mechanisms.

Controls Over the Peripheral Circulation

Neural Control

Neural control of the systemic circulation allows rapid regulation of the circulation and provides simultaneous control of different parts of the peripheral circulation. It is the primary mechanism responsible for the minute-to-minute control of blood pressure and regional blood flow distribution in the resting state and in response to acute stresses. Neural regulation consists of feedback information (afferent limb) provided by various mechanoreceptors and chemoreceptors, central integration of that information in the medulla oblongata, and effector mechanisms (efferent limb) within the autonomic nervous system, composed primarily of sympathetic nerves. Nearly all blood vessels in the body are innervated by the sympathetic vasoconstrictor nerves; some are also innervated by sympathetic and parasympathetic vasodilator nerves. The extent and type of innervation vary from one vascular bed to another.

The primary afferent limb of the neural control mechanisms consists of mechanoreceptors in the carotid sinuses and aortic arch, which respond to changes in pressure (baroreceptors). Two types of baroreceptors have been identified. Type 1 receptors control dynamic changes in blood pressure; type 2 receptors are responsible for control of resting blood pressure (23). These receptors respond to mechanical stretch of the arterial wall and send nerve impulses to the cardioinhibitory and vasomotor centers of the medulla oblongata. Stimulation of carotid sinus receptors results in slowing of heart rate, vasodilation, and a decrease in arterial blood pressure. Smooth muscle in the walls of these baroreceptor regions is innervated by vasoconstrictor efferent fibers, suggesting that sympathetic activity may modify baroreceptor responses.

Mechanoreceptors are also found in the walls of the atria and ventricles. These receptors are located in the walls of both atria at the venoatrial junctions (24), and are scattered throughout the left ventricle and interventricular septum. Two kinds of atrial receptors have been described. Type A receptors fire during atrial contraction and respond to changes in atrial pressure, and type B receptors fire during ventricular systole and respond to changes in atrial volume (25). Type A receptors stimulate and type B receptors inhibit sympathetic vasoconstrictor activity. These receptors provide feedback to the hypothalamus and inhibit secretion of antidiuretic hormone (vasopressin) (25). Atrial stretch causes secretion of atrial natriuretic peptide (ANP), which is discussed in more detail later. Atrial receptors also alter sympathetic stimulation of the renal circulation (23). By these mechanisms, atrial stretch receptors play an important role in regulation of intravascular volume. They are also responsible for the increase in heart rate caused by the Bainbridge reflex (24).

Two different types of mechanoreceptors are found in ventricular myocardium. The first fire in a pulsatile manner in time with cardiac rhythm and are small in number. The second respond to mechanical stimulation and to various drugs and chemicals through nonmyelinated afferent nerves known as C fibers (24). Stimulation of C fibers, primarily located in the left ventricle, causes hypotension and bradycardia by parasympathetic stimulation and sympathetic inhibition (24). There is evidence to suggest that carotid baroreceptors are more important for control of sympathetic regulation of muscle blood flow, whereas cardiac receptors are more important for control of sympathetic regulation of kidney blood flow.

Chemoreceptors also play a significant role in the central control of the circulation, particularly during acute stresses. Under normoxemic and normocapnic conditions, they exert little effect, but hypoxemia and hypercapnia increase sympathetic vasoconstrictor activity in addition to stimulating respiratory rate and effort. The primary locations of these chemoreceptors are in the carotid body, aortic arch, and brain (the latter is likely the mechanism of the Cushing reflex), but they also exist in coronary vessels, muscle, and lung.

Central integration of neural control of the circulation occurs primarily in the medullary cardiovascular centers, which also control respiration. Higher centers, such as the hypothalamus, modulate the medullary activity. The only afferent component that appears to have continuous input to the central control is the arterial baroreceptors.

Central mechanisms in the medulla control the efferent output of the sympathetic and parasympathetic neural systems, the efferent limb of neural control of the circulation. The primary efferent effectors are the sympathetic vasoconstrictor fibers. Their nerve endings contain the vasoconstrictor norepinephrine, which is released on nerve stimulation. They innervate the "resistance vessels," which are systemic arterioles that constrict upon this sympathetic stimulation. Other substances are present at the neurovascular junction, including monoamines, polypeptides, purines, and amino acids, all of which can influence the release and the effects of norepinephrine (23). Impulses carried through vasoconstrictor fibers contribute the normal vascular tone or baseline constriction that is present at rest in most vascular beds and thus are the main mechanism for regulating blood pressure in the unstressed state. These vasoconstrictor fibers are more prevalent in skeletal muscles, where intrinsic tone is fairly high under resting conditions. They are much less prevalent in the cerebral and coronary beds. Sympathetic vasoconstriction of larger arteries and of veins changes their volume and therefore changes the circulating volume; these vessels are known as capacitance vessels.

Sympathetic stimulation by vasodilator fibers increases blood flow to a vascular bed. These fibers are primarily found in the vascular beds of skeletal muscle. The transmitter in vasodilator fibers is thought to be acetylcholine, although in primates it may be epinephrine. These vasodilator fibers may cause a small anticipatory increase of blood flow to the skeletal muscle. However, once muscle exercise begins, local vasodilation probably plays a more important role.

The parasympathetic system primarily controls heart function and rate and has a very limited role in control of the peripheral circulation. The transmitter stored in nerve endings of the parasympathetic system is acetylcholine. Parasympathetic vasodilator fibers are found in the cerebral and myocardial circulations and in the bladder, rectum, and external genitalia. Their effects are important for local vasodilation in the latter group, but have very little role in vascular tone in the brain and the heart.

Hormonal Control

Hormonal control of the peripheral circulation can best be described as vascular constriction or dilation in response to circulating hormones. The vasculature in the peripheral circulation is responsive to various hormones, including catecholamines, angiotensin II, vasopressin, eicosanoids, NO, and peptide hormones.

Catecholamines are the hormones of the adrenergic system. Adrenergic receptors to catecholamines are present in the smooth muscle throughout the peripheral vascular system and can be categorized as α and β receptors. Stimulation of α receptors causes vascular smooth muscle to contract, causing vasoconstriction; stimulation of β receptors causes vascular smooth muscle to relax, causing vasodilation. These receptors

are responsive to both endogenous catecholamines and sympathomimetic drugs. Norepinephrine, an α -adrenergic agonist, is secreted by the adrenal medulla and is carried by the bloodstream to receptors in the peripheral vasculature. Preganglionic sympathetic fibers innervate the adrenal medulla and stimulate norepinephrine secretion. There is, therefore, central control of this hormonal regulation. Epinephrine is also secreted by the adrenal medulla, but it is a much weaker vascular stimulant and tends to exert a β -agonistic effect at physiologic concentrations.

Angiotensin II, a powerful vasoconstrictor, is produced by activation of the renin-angiotensin-aldosterone system. The juxtaglomerular apparatus in the kidney secretes renin in response to decreased renal arterial pressure or a decrease in extracellular fluid volume. Renin, in turn, cleaves angiotensinogen to angiotensin I, which is then converted to angiotensin II by a converting enzyme found in lung and vascular endothelium. Angiotensin II has direct vasoconstrictor properties, acts centrally to stimulate the vasoconstrictor centers of the brain, and stimulates the secretion of antidiuretic hormone (vasopressin). Antidiuretic hormone is synthesized in the hypothalamus and secreted by the posterior pituitary. It is a very potent vasoconstrictor but plays a minimal role in regulation of the circulation under resting conditions.

Prostaglandins and other eicosanoids play a small role in regulation of flow in the systemic circulation and have been discussed in detail above. Another group of hormones that participate in regulation of the systemic circulation are the natriuretic peptides. At the present time, the three main natriuretic peptides are ANP (atrial natriuretic peptide), BNP (brain natriuretic peptide), and CNP (C-type natriuretic peptide), although new members of this family are continually being discovered. ANP is released from atrial myocytes of both atria and in smaller amounts from the ventricular myocytes. Ventricular production of ANP decreases with maturation; large amounts of ANP are produced in fetal ventricular myocardium, and only small amounts are produced by adult ventricles (26). ANP is released in response to stretch of either atrium. Increased circulating levels of ANP are detected when left atrial pressure is elevated even when the right atrial pressure is normal. In the kidney, ANP decreases tubular reabsorption of sodium. In the circulatory system, ANP has vasodilator and cardioinhibitory effects (26). Circulating levels of ANP are increased in certain pathophysiologic conditions, such as congenital heart disease associated with elevated atrial pressures, congestive heart failure, valve disease, hypertension, coronary artery occlusion, and atrial arrhythmias (26). BNP is secreted from the ventricles, responding to volume expansion and pressure overload similarly to ANP. Its mechanism of action is also similar, binding to BNP receptors which subsequently causes an increase in intracellular cGMP levels. BNP is important because it has been found to be one of the most specific and sensitive biomarkers for heart failure. CNP is quite different than ANP and BNP. It is thought to be stored locally, in endothelial cells, particularly in the coronary and mesenteric circulations. It acts via G_i proteins to inhibit adenyl cyclase and activate phospholipase-C. It hyperpolarizes smooth muscle cells, leading to vasodilation, and is thought by some investigators to be the endothelium-derived hyperpolarizing factor (EDHF) discussed below (27).

Endothelial Function

The vascular endothelium plays an important role in regulating vascular tone, platelet adhesion, and inflammation. Receptors are present on the endothelial cell membrane for a number of locally produced and remotely secreted hormones and other substances, including peptides, kinins, amines, nucleotides, and eicosanoids. The endothelium responds to changes in

blood flow and stretch and generally promotes vasodilation (28). The endothelium produces vasoactive substances in response to different stimuli to mediate this effect.

Vasodilator substances produced by the endothelium include PGI_2 , EDNO, adenosine, and EDHF (28). PGI_2 and EDNO have been discussed above. The identity of EDHF has yet to be determined but many investigators think that it is CNP. It produces hyperpolarization of vascular smooth muscle cells (28) by activating K^+ channels, thereby inhibiting voltage-gated calcium channels, lowering cytosolic calcium, and promoting relaxation (29). Vasoconstrictor substances produced by the endothelium include ET-1, a locally acting peptide hormone also discussed earlier in this chapter. Angiotensin II is also produced in the endothelium by angiotensin-converting enzyme, found in vascular endothelial cells. Other vasoconstrictor factors are postulated to be produced by the endothelium, but are yet to be identified (28).

Local Metabolic Control

In addition to local endothelial release of vasoactive hormones described above, tissues have the ability to regulate their own blood flow in response to changes in metabolic demands by changes in their chemical milieu. The local chemical environment of arterioles can cause vasodilation or, to a lesser extent, vasoconstriction. For example, a decrease in pO_2 , an increase in pCO_2 , or an increase in H^+ or K^+ concentration each causes arteriolar vasodilation independent of endothelial function. Many cells other than endothelial cells will release adenosine, a potent vasodilator, in response to increased metabolism or decreased oxygen tension.

Red Blood Cell Control

Recently, red blood cells have been postulated to be a major factor in the regulation of local blood flow (30). It has been proposed that the sensor is deoxygenated hemoglobin. By a variety of mechanisms, deoxygenation may cause the release of vasodilatory compounds from the red blood cell, or may cause the red blood cell to release factors that stimulate endothelial release of vasodilatory compounds. Three possible mechanisms of this action have been proposed. First, red blood cells have been shown to be able to release ATP in a deoxygenation-dependent manner; this, in turn, is capable of promoting the endothelial production of NO and other local vasodilators. An important finding is that ATP can be propagated upstream, which is necessary if deoxygenated red blood cells in capillaries are to be capable of inducing arteriolar dilation. Second, there is evidence of direct red blood cell release of NO from S-nitrosohemoglobin on deoxygenation. NO is rapidly inactivated in red blood cells by interacting with oxygenated hemoglobin to form methemoglobin and nitrate, and it binds to deoxygenated hemoglobin to form nitrosylhemoglobin. It is thought that the latter compound contains some vasodilatory potential, carried in red blood cells in the S-nitrosohemoglobin form. Lastly, it has been proposed that small amounts of local nitrite produced by NO oxidation can react with deoxygenated hemoglobin, when taken up in the red blood cell, to produce NO, which then escapes from the cell.

Autoregulation

Blood flow to tissues remains relatively constant over a wide range of arterial blood pressure owing to autoregulation. The mechanisms of this phenomenon are largely unknown. Several hypothetical mechanisms exist, including local metabolic control, myogenic activity of vascular smooth muscle, tubuloglomerular feedback in the kidney, and tissue pressure. These mechanisms may act alone or in combination. The metabolic hypothesis suggests that blood flow is closely linked to tissue

metabolism. Reduction of inflow of blood would cause an accumulation of vasodilator substances such as those discussed above, which would in turn cause vasodilation and increased blood flow. In organs with high oxygen consumption, autoregulation of blood flow is dependent on tissue oxygenation. A second proposed mechanism of autoregulation is myogenic control (31). According to this theory, increased intravascular pressure stimulates vasoconstriction of vascular smooth muscle. A venous-arterial reflex has been described in which an increase in venous pressure causes arteriolar constriction, probably by a neurally mediated mechanism (31). A tubuloglomerular feedback mechanism may help to autoregulate renal blood flow. According to this hypothesis, increased renal blood pressure and flow increase the concentration of solutes in the tubular fluid; this increase is sensed in the macula densa, causing vasoconstriction by an unknown mechanism. Tissue pressure is another possible mechanism for autoregulation. By this proposed mechanism, increased tissue pressure in areas in encapsulated organs or in the brain leads to decreased blood flow to those areas. Autoregulation seems to play a more significant role in control of resting blood flow in vital organs such as the brain and heart and becomes significant in other areas during times of increased metabolic demand.

Specific Regional Vascular Beds

The different regional vascular beds in the fetus and child are controlled to varying extents by the different mechanisms discussed above. Generally, the highly metabolically active organs such as the brain and heart are primarily regulated by local mechanisms, whereas the less active beds are under central neural and hormonal controls. Specialized beds such as the renal and hepatic circulations, which receive blood for unique activities such as metabolic degradation and excretion, hematopoiesis, and blood pressure control, have unique combinations of control mechanisms. The myocardium is not discussed in this section because it is considered elsewhere (see Chapter 3).

Cerebral Circulation

The cerebral circulation of the fetus and neonate has been the most extensively studied and characterized. It is unique in four main respects. First, there is a blood-brain barrier created by a continuous lining of endothelial cells linked by tight junctions and by degradative enzymes; thus, changes in circulating concentrations of various constituents such as H^+ and catecholamines may have a limited effect. Second, the large arteries form a significant component of the resistance circuit, having been shown to respond in a similar fashion to the arterioles in response to stresses such as hypoxia (32). Third, the cerebral circulation is encased in a closed box, the skull, so that perfusion pressure is particularly important to blood flow characteristics. And fourth, there is great heterogeneity in blood flow patterns to the different regions of the brain. They have very different resting blood flows and are controlled to different extents by different mechanisms. For example, in the fetus, the greatest blood flow occurs in the oldest regions phylogenetically: The brain stem receives the most, then the cerebellum, and last, the cortex. In the newborn, the pattern is immediately reversed, with the cortex receiving the greatest blood flow, then the cerebellum, and last, the brain stem (33). These differences are thought to exist because of differences in sensitivity to hypoxia and hyperoxia.

Autoregulation is an essential component in the control of cerebral blood flow. To limit the risk of hemorrhage and inadequate blood supply to the brain in the face of acute increases and decreases in blood pressure, it is important that flow remains constant over a wide range of perfusion pressures in the range of 60 to 160 mm Hg. At higher blood pressure,

autoregulation is lost, and blood flow becomes dependent on mean arterial pressure. At pressures below the autoregulation range, cerebral blood flow falls resulting in ischemia (34).

In the brain, several mediators of autoregulation have been found. It appears that alterations in local adenosine concentrations mediate the autoregulatory response. Interstitial levels of adenosine increase during hypotension, an adenosine analogue increases blood flow in the autoregulatory range, and autoregulation is abolished by blocking the adenosine receptor (35). Prostanoids are another group of vasoactive substances that have been implicated in the control of autoregulation. Dilator prostanoids such as prostacyclin increase in response to hemorrhage, and cyclooxygenase inhibition decreases cerebral blood flow and the response to hypotension. There is evidence that neuronally derived NO participates in vasodilation during hypertension (36). Whether or not NO plays a role in autoregulation of cerebral blood flow is still controversial (37).

Autoregulation has been demonstrated in young fetal sheep as early as 93 days' gestation (~ 0.67 gestation) and exists over a wide range of mean cerebral arterial pressures (35). However, the lower limit of this range is close to the normal mean perfusion pressure, putting the fetus at relatively high risk for hypotension-associated problems. This is particularly important in the subependymal germinal matrix, which exists until about 36 weeks' gestation in the human fetus, and in the choroid plexus, which are the primary sites of intraventricular hemorrhage in the premature infant. In the sick preterm and term infant, autoregulation has been shown to be absent (38), a circumstance that may predispose these infants to brain injury such as intracranial hemorrhage. At birth, studies are conflicting as to whether the autoregulatory range increases significantly. However, the lower limit of the autoregulatory range is much further below the normal mean perfusion pressure than it is in the premature infant.

Another major regulating factor of cerebral blood flow is blood oxygen concentration. Because of the critical importance of oxygen delivery to the brain, this is not surprising. However, although it had been assumed that pCO_2 is a more important determinant of cerebral blood flow, studies have shown that the fetus and newborn are relatively insensitive to pCO_2 changes but can change blood flow twofold to threefold in response to changes in arterial pO_2 (35). In the immature brain, oxygen sensitivity follows the same hierarchy as flow patterns. The brain stem is most sensitive and the cortex is least sensitive to changes in pO_2 . This is perhaps a protective mechanism to permit the maintenance of basic autonomic function during profound hypoxia. The mechanisms behind oxygen sensitivity are not certain, although local factors produced by the endothelium probably play a considerable role. In addition to vasoactive substances, oxygen may have a direct effect on various ATP-mediated reactions (32).

Carbon dioxide also has a significant effect on cerebral blood flow, although less than in the mature brain, and, like oxygen, has its greatest effects on the brain stem (33). Moreover, this effect has been demonstrated in all regions of the brain as early as 0.4 gestation in the fetal sheep (39). Because of the blood-brain barrier, this effect is specific to a change in pCO_2 ; cerebral blood flow does not change in the face of metabolic acidosis or alkalosis. The effect of pCO_2 appears to be exerted by changing extracellular brain H^+ , but how this change in H^+ then affects the production or release of endothelium-derived vasoactive substances is not known. It is apparent, however, that prostanoids are significantly involved in this response (40). Recent evidence has demonstrated that hypoxia disrupts cerebral autoregulation, but hypocapnia augments the cerebral autoregulation response (41).

Other factors also can modulate cerebral blood flow, including sympathetic innervation, circulating hormones such

as vasopressin and catecholamines, and blood hematocrit level, but it is clear that this highly metabolically active organ is under exquisite control from very early in gestation by a host of local regulatory mechanisms.

Peripheral Tissues

In contrast to the cerebral circulation, the peripheral circulation (skin, muscle, and bone) is primarily under central control. The vasoactivity of each component of the peripheral tissues is controlled somewhat differently. For example, the skin is predominantly under α -adrenergic tone with no significant autoregulation, whereas the muscle has a higher proportion of β -adrenergic control and has intact autoregulation. This group of vascular beds is presented together because the primary control of vascular tone of these beds and the responses to major stresses such as hypotension and hypoxemia are similar and are predominantly mediated by the autonomic nervous system and circulating hormones. Because peripheral blood flow is needed primarily for growth and thermoregulation in the developing organism and essential oxygen demands are small, central controls that limit flow during stress can be invoked with few sequelae. Thus, from early fetal life, a large variety of vascular receptors develop, including α_2 -adrenergic, β_1 - and β_2 -adrenergic, dopaminergic A1 and A2, vasopressinergic V1, Endothelin A and B, muscarinic, etc. They transduce alterations in levels of circulating and synaptic compounds via various intracellular second messengers, into alterations of peripheral vascular smooth muscle tone.

Early in gestation, the peripheral circulation is predominantly under α -adrenergic influences, with little cholinergic tone. Changes in basal tone can be demonstrated with the administration of α -adrenergic agonists and not by β -agonists or cholinergic agents. Similarly, blocking of α -adrenergic activity invokes a large decrease in peripheral vascular resistance, whereas the dominant effect of β -adrenergic blockade is to slow heart rate. Although parasympathetic tone is limited in early gestation, receptors are present and can be stimulated. Late in gestation, resting activity increases rapidly toward the high levels normally seen after birth. Very early in fetal life, response of autonomic receptors requires that circulating catecholamines be secreted by the adrenal medulla and nonadrenal chromaffin tissue; innervation is a significantly later event than receptor development. As innervation proceeds rapidly in early fetal life, neural mechanisms can be invoked to alter peripheral blood flow. The primary neural mechanisms invoked are the central vasomotor controls, which are primarily medullary, peripheral baroreceptors located in the carotid sinus and peripheral chemoreceptors located in the carotid and aortic bodies. Activity of both the baroreceptor and chemoreceptor mechanisms has been documented early in gestation, and although the manifestations may be blunted by the existence of central shunts and the umbilical-placental circulation, peripheral vasoconstriction is evident. The critical importance of baroreceptor control of the peripheral circulation is demonstrated by the marked fluctuations in arterial blood pressure induced by sinoaortic denervation in immature fetal sheep (42).

In addition to circulating catecholamines and the autonomic nervous system, other circulating hormones exert significant effects on the peripheral circulation throughout fetal and postnatal life. The renin-angiotensin system probably plays a major role in controlling peripheral vascular tone even in the young fetus; infusion of angiotensin II significantly increases peripheral vascular resistance (43). Plasma vasopressin increases during hypotension in the fetus and the newborn (44). Although ANP has been demonstrated as early as 21 weeks in the human fetus and does appear to have a small effect on blood volume, there is no evidence of a peripheral vascular effect (45).

NO plays a role in vasodilation of the skin and muscle, but its role is limited. In response to whole-body heating, NO contributes about 30% of the vasodilation of the skin (46). In contrast, with local heating, NO is primarily responsible for vasodilation. During exercise, NO also plays a modest role in increasing peripheral blood flow for local homeostasis. There is a balance achieved between local vasodilation, sympathetic vasoconstriction, and whole-body blood pressure control (46) to allow maintenance of local homeostasis and central blood pressure. NO plays no significant role in blood pressure control during exercise.

Last, circulating hormones can affect the peripheral circulation indirectly via their effects on the central nervous system as well as in peripheral autonomic ganglia and the adrenal medulla. The roles of vasopressin and angiotensin II in the central control of the peripheral circulation are not clear, but these agents, along with various neurotransmitters, apparently exert significant controls via stimulation and inhibition of various central regions. Endogenous opioids are intimately involved in the cardiovascular response to shock by exerting both central and adrenal medullary effects in the adult. Endogenous opioids at concentrations higher than those seen in the mother have been demonstrated throughout gestation, and fetal plasma β -endorphin levels have been shown to increase in response to maternal hypoxemia (47).

Renal Circulation

Aspects unique to the renal circulation are its exceptionally high blood flow because of the requirements of glomerular ultrafiltration, the presence of two distinct capillary beds to allow filtration and reabsorption, and the delayed maturational processes in regional blood flow and its controls as compared with other systemic vascular beds.

Blood flow to the adult kidney represents up to 25% of cardiac output. Most of this flow courses via the afferent arterioles in the renal cortex to the glomerular capillary bed. This capillary bed is under relatively high pressure to allow for a large production of ultrafiltrate into the renal collecting system. Distal to an efferent arteriolar system that significantly decreases hydrostatic pressure, significantly less blood passes to the medullary capillary bed. This low pressure in addition to osmotic forces favors the reuptake of the filtrate. Within the two regions, the cortex and medulla, there is preferential distribution of blood as well. The outer cortex receives a relatively small proportion of cortical blood and is composed of small glomeruli with low single-nephron glomerular filtration. The inner or juxtaglomerular cortex receives far more blood flow per weight and is composed of very large glomeruli with high filtration rates. The medulla is composed of the outer medulla (the descending and thick ascending limbs of the loops of Henle and collecting duct segments) and the inner medulla (thin segments of the loops of Henle and the terminal portions of the collecting system). The inner medulla is perfused by the vasa recta and receives the least blood per weight and at very slow transit times. This is critical to the reuptake of ultrafiltrate and thus concentration of urine: There is an inverse relationship between inner medullary blood flow and urine osmolality.

Under normal conditions, the primary mechanism for control of renal cortical blood flow is autoregulation, which matures quite late. Autoregulation in the kidney consists of two mechanisms, tubuloglomerular feedback and renal myogenic response (48). Tubuloglomerular feedback involves sensing flow in the region of the macula densa that results in alteration in vascular tone in adjacent arterioles, likely involving adenosine or ATP. Myogenic response refers to vasoconstriction of afferent renal arterioles in response to increased transmural pressure. Both mechanisms participate in regulation of renal flow and protection from renal injury from hypertension (48).

Autoregulation is present in the newborn of most species but is of reduced efficiency. Because the immature kidney excretes far more prostanoids than the mature kidney, it is possible that impaired autoregulation is caused not so much by an immaturity of the mechanisms controlling autoregulation as by an overabundance of prostanoid production. In normal conditions, however, there is no evidence that prostanoids play a role in the control of renal blood flow. A mechanism unique to the kidney that contributes to autoregulatory control of renal blood flow is tubuloglomerular feedback. This mechanism is a single-nephron phenomenon and is initiated by alterations in filtrate and solute flow from the proximal to distal tubule. An alteration in either distal tubule reabsorption or fluid delivery alters the blood flow and glomerular filtration, probably by constriction or dilation of the afferent arteriole. The renin-angiotensin system mediates afferent arteriolar vasoconstriction so that glomerulotubular feedback depends on an intact and mature juxtaglomerular apparatus and renin-angiotensin system. The immature kidney does not show tubuloglomerular feedback until after birth, probably because of an immature renin-angiotensin system. In addition to the elevated renal prostanoids already discussed, basal levels of angiotensin II are elevated so that the ability of the juxtaglomerular apparatus to further activate the system is greatly limited; moreover, the immature renal vasculature is relatively insensitive to the constrictor effects of angiotensin II. Thus, unlike in the cerebral circulation, fine control of renal blood flow in resting conditions is significantly impaired in the fetus and newborn.

During stress, however, autonomic rather than autoregulatory mechanisms predominate and act primarily to limit renal blood flow. Both α_1 - and α_2 -adrenergic receptors are present in the kidney throughout fetal and postnatal life, and stimulation of both by neural discharge or circulating catecholamines causes renal vasoconstriction, redistributing blood away from the kidney as blood is distributed away from the peripheral circulation. Dopaminergic and β -adrenergic receptors are also present across development, although dopamine-2 receptor density decreases with age (49). Stimulation of both causes vasodilation but their physiologic significance is uncertain in the immature kidney. There is no evidence of resting β -adrenergic tone, and β -adrenergic blockade does not enhance α -adrenergically mediated vasoconstriction in the fetal sheep. However, the adult is more sensitive to stimulation of both β -adrenergic and dopaminergic receptors, developing significantly more vasodilation.

The role of other circulating factors in the control of cortical blood flow in the young is less significant and often less clear. The renin-angiotensin system has been discussed in regard to autoregulation. Although it is very important to the autoregulatory ability of the adult kidney, the renin-angiotensin system has significantly limited effects on autoregulation in the very young. Although captopril increases renal blood flow in the newborn lamb (50), this may be caused by its inhibition of kininase II in the kallikrein-kinin system, rather than by inhibition of angiotensin-converting enzyme. Similar to angiotensin, vasopressin is not known to have effects on resting renal blood flow in the young (51), despite the presence of V1 receptors.

Control over medullary flow in the adult kidney is primarily by vasopressin, with no evidence of autoregulation. As medullary flow decreases in response to release of vasopressin, the osmotic gradient increases and uptake of the resorbate increases. As mentioned, the medulla consists of two distinct zones with complex vasculature to allow the countercurrent multiplication and exchange critical to the reuptake of the vast majority of the ultrafiltrate. It is in the inner medulla that the extreme concentration of the urine occurs and the greatest sensitivity to vasopressin exists.

In addition to regional and developmental differences in the control of cortical and medullary blood flow, there are significant developmental differences in intrarenal regional blood flows and flow distribution, as suggested above. Up to 25% of cardiac output is distributed to the kidney in the adult, with about 90% of that flow being cortical. Most of that cortical flow is distributed to the larger juxtamedullary nephrons, yielding a very high glomerular filtration rate. Conversely, the immature kidney receives far less blood, and the distribution of that blood is less specific. The very low cortical flow is associated with a markedly reduced glomerular filtration rate in the fetus and newborn, and the relatively high medullary flow with limited vasopressin sensitivity is associated with poor concentrating ability. The lesser renal blood flow is caused only in small part by fewer nephrons. Glomerulogenesis is complete in the human by 36 weeks' gestation, yet the kidneys still account for only about 5% of cardiac output at birth. Over the first weeks of life, both renal blood flow and glomerular filtration rate double as afferent arteriolar resistance decreases. The ultimate increase in renal blood flow and ultrafiltration is related to further alterations in the renal vasculature, particularly in conjunction with the large increase in the size of glomeruli, which is not complete until late adolescence.

In summary, the renal vascular and glomerular beds are very immature at birth, so that renal function and control over renal blood flow and its distribution are limited. Throughout much of childhood, maturation proceeds, although most is accomplished in the first few months of life. The control mechanisms of renal flow are centered on three requirements: maintenance of adequate ultrafiltration in the cortex, maintenance of filtrate concentration in the medulla, and redistribution of blood away from the kidney in periods of stress. The three functions are primarily controlled by different mechanisms that mature at different rates.

Splanchnic Circulation

The splanchnic circulation consists of the vascular beds of the spleen, gastrointestinal tract, and liver. Similar to the renal circulation, the splanchnic circulation receives about 25% of cardiac output in the adult, but it is also a large reservoir of blood, containing about 20% to 25% of total blood volume. Thus, response to stresses such as hemorrhage leads not only to redistribution of blood flow away from the splanchnic circulation but also to mobilization of blood volume from that vascular bed to the central vessels and other organs. Control over the splanchnic bed in response to stress is primarily central rather than local, with neurohumoral catecholamine stimulation being the major mechanism controlling vasoconstriction. Stimulation of both carotid and aortic baroreceptors causes sympathetic neural stimulation of splanchnic resistance and capacitance vessels and large decreases in splanchnic blood flow and volume. Also, secondary to the active vasoconstriction of the resistance (arterial) component of the splanchnic circulation are decreases in the venous capacitance size. It appears that approximately half the decrease in splanchnic blood volume is secondary to active vasoconstriction of the capacitance (venous) system and half secondary to its passive decrease in volume. Specific to the splanchnic bed is the property that exercise and thermal stresses also induce large decreases in flow and volume with redistribution to the skeletal muscle and skin, respectively. The afferent limbs of these responses are uncertain because, unlike with hemorrhage, stimulation of baroreceptors does not occur. Responses specific to the individual components of the splanchnic vascular bed are discussed next.

The spleen has significant sympathetic adrenergic innervation and responds to stimulation with vasoconstriction. Although there are β -adrenergic receptors as well as

α -adrenergic receptors, the former are less active. In addition to sensitivity to adrenergic stimulation, human splenic arterioles respond to vasopressin and angiotensin with vasoconstriction. There is no evidence of autoregulatory or other local controls over splenic blood flow. Thus, in response to stress, central mechanisms direct blood flow away from the spleen. Unlike other mammals, humans do not show significant reduction in splenic venous capacitance with stimulation, so it does not contribute significantly to the blood reservoir when mobilized with stress. It is the other components of the splanchnic circulation that contribute to increasing blood volume during hypovolemic stresses.

The gastrointestinal tract has a more complex vascular bed, controlled by a greater variety of mechanisms. Like the splenic vessels, the mesenteric vessels are richly innervated with sympathetic nerves, which respond to stimulation with vasoconstriction, although there are some vasodilatory β -adrenergic receptors as well. Constriction of the venous effluent vessels in addition to the passive decrease in venous capacitance causes mobilization of blood volume from this large reservoir. The intestinal circulation also responds similarly to the splenic circulation during hemorrhage, with marked vasoconstriction in response to increases in angiotensin II and vasopressin. However, unlike the splenic circulation, the intestinal circulation escapes from vasoconstriction as vascular resistance decreases and flow increases secondary to autoregulatory escape. This escape phenomenon is not well defined, but it is probably secondary to sensitivity of the arteriolar bed to vasodilator metabolites such as adenosine, in much the same way that adenosine is involved in local regulation of other vascular beds, such as the cerebral and myocardial circulations. This metabolic mechanism may explain why the fed adult dog, which has a greater oxygen extraction under normal pressure, exhibits better autoregulation than the fasted dog. This greater local regulatory response during conditions of greater oxygen extraction is also evident in the young (35 days) pig during hypoxic and ischemic stresses (52). However, similar to but not as pronounced as the case in the renal vascular bed, autoregulatory mechanisms are immature in the newborn, both at rest and in hypoxic and ischemic conditions.

The response of the intestinal circulation to feeding is also of interest. In anticipation of food, the response is central in origin and largely sympathetic, causing vasoconstriction. Once food has been ingested, there are major local vascular responses related to the type of food, the products of digestion in different parts of the intestine, and the secondary effects of various gastrointestinal hormones. The hydrolytic products of carbohydrates and fat are particularly potent local vasodilators and appear to act on a metabolic basis similar to that of autoregulation by increasing local oxygen consumption. Local hormones that may play a role in vasodilation include cholecystokinin, secretin, gastrin, glucagon, and vasoactive intestinal polypeptide. The overall response to feeding yields increases in local blood flow of $\leq 300\%$ within 60 to 90 minutes (53). Because of the large increase in oxygen consumption, however, these increases are not enough to meet the increased metabolic demand, so that oxygen extraction also increases.

The hepatic circulation is even more complex, receiving both highly oxygenated blood from the hepatic arteries and blood of lesser saturation but greater substrate concentrations from the portal vein. The incorporation of umbilical venous blood in the fetal circulation was discussed earlier. A review by Lauth and Greenway (54) clearly describes the hepatic circulation and its control. The portal vein terminates in the hepatic sinusoids, and the hepatic arterioles split into a complex capillary network that also drains into the sinusoids. These vessels, along with the biliary ductules and lymph vessels and nerves,

occupy the portal triad. In these sinusoids, which allow free contact with the hepatic cells, the blood passes radially away from the center of the hepatic glomus to the periphery, where it passes into the hepatic venules on its way to the hepatic veins and inferior vena cava. As the blood passes from the center (zone 1) to the periphery (zone 3), near the hepatic venules, different metabolic activities predominate.

As with the kidney, blood flow to the liver is large (about 25% of cardiac output in the adult) and far exceeds its metabolic demand for oxygen. As with the intestinal circulation, hepatic blood volume is large (about 10% of total blood volume) and is mobilized during periods of stress. Conversely, as hepatic venous pressure increases, hepatic blood volume increases greatly because of the large compliance of these capacitance vessels. There are also sphincters described in the hepatic venules that may regulate hepatic blood volume by varying sinusoidal volume and portal resistance. These sphincters respond to norepinephrine and angiotensin.

Portal venous blood contributes about 75% of hepatic blood flow, and this flow is determined primarily by mechanisms that regulate splenic and intestinal flow, although presinusoidal sphincters exist as well. Alterations in hepatic venous pressure affect neither portal flow nor its intrahepatic distribution. The hepatic arterial circulation is innervated in a similar fashion as the mesenteric arterial circulation and responds prominently to α -adrenergic stimulation during stress, as well as to other stress hormones such as angiotensin II and vasopressin. Similarly, there are vasodilatory β_2 -adrenergic receptors and there is some responsiveness to vasodilatory gastrointestinal hormones such as glucagon, secretin, and pentagastrin. An additional regulatory mechanism of hepatic arterial flow exists that is somewhat analogous to intestinal autoregulation. Although there is no autoregulation within the arterial circulation, as portal venous flow decreases, there is a reciprocal increase in hepatic arterial flow. The mechanism is thought to be adenosine regulated. Adenosine is released into the central sinusoids and comes in contact with the hepatic arterioles; as portal flow decreases, the washout of adenosine from this region is decreased, and thus more is present to dilate the hepatic arterioles (53).

Perhaps the largest changes in regional blood flow in the perinatal period occur in the liver, but this is not because of maturation of the hepatic circulation but rather because of loss of the umbilical-placental circulation. Prior to birth, the primary source of hepatic blood flow is the umbilical vein, which joins the portal venous blood in the portal sinus. About 45% of umbilical venous return passes to the liver, with the right lobe receiving somewhat more than the left (4). Portal venous blood is distributed much more unequally, with almost all of it passing to the right lobe, which therefore is perfused with blood of much lower hemoglobin oxygen saturation compared with the left. Hepatic arterial blood flow is very limited in the fetus and is distributed approximately equally to the two lobes. At birth, the loss of the umbilical-placental circulation is not associated with immediate closure of the ductus venosus, which can remain patent for several days (25). Some portal venous blood is shunted away from the liver to the inferior vena cava via the ductus venosus. This, along with the absence of an immediate increase in hepatic arterial flow causes a marked reduction in hepatic blood flow at birth and a halving of oxygen consumption (2). By 1 week of age, hepatic blood flow increases and oxygen consumption returns to fetal levels, although hepatic arterial blood flow remains at the very low fetal levels, contributing only 5% of total hepatic blood flow. The mechanisms that underlie the increase in hepatic flow and oxygen consumption in early postnatal life and the subsequent increase in hepatic arterial flow are uncertain, as are the implications of these changes on liver function and maturation.

Diagnostic and Therapeutic Methods

History and Physical Examination

Steven C. Cassidy ■ Hugh D. Allen ■ John R. Phillips

Despite the availability of advanced imaging technologies, a thorough history and physical examination is the core of evaluating children with suspected heart disease. Although the basics of obtaining a history and physical examination are similar in all patients, this chapter emphasizes specific issues when evaluating a child with possible cardiac pathology.

HISTORY

To obtain an accurate history, it is important to establish rapport with the patient and parents. Meetings are often short and first impressions are lasting, so the first encounter is critical. The examiner should sit and carefully listen to the details provided by the patient and parents. The history is the predominant vehicle that defines the first encounter. *Many aspects of the history are age specific. Therefore, historical information should be elicited from the patient, as age and maturity allow, and from the parents as observers*

Parents often research their child's illnesses on the Internet or through the media and may come to a visit with preconceived notions and, perhaps, opinionated or anecdotal information. The examiner must be prepared for this and discuss the patient's condition in a nonconfrontational and open manner. In that way, an honest and positive patient-physician relationship will be established.

Newborns and Infants

Congenital heart disease often presents in early infancy because of observed abnormalities in the appearance or behavior of the infant. Because an infant's primary physical exertion is eating, a thorough feeding history should be obtained. If the mother has had previous children, she may offer insight into differences in feeding habits between the patient and her other children. The feeding history should be as quantitative as possible. Frequency of feeding, volume of milk or formula (and type of formula,

especially regarding kcal/oz information) consumed, and the length of time to finish a feeding should be obtained for both bottle- and breast-fed infants. Most newborns feed 2 to 3 oz every 2 to 3 hours. It is common for children with congestive heart failure to take breaks during a feeding because of rapid breathing or to fall asleep during feeding only to awaken after a few minutes and feed a small amount again. Generally, normal infants should be able to complete their feeding in <30 minutes. A longer time to finish each feeding, low volume consumed, excessive diaphoresis, and increased work of breathing during feeding are signs of heart failure or poor cardiac output. As pulmonary vascular resistance declines over the first 4 to 6 weeks of life, irritability and fussiness with feeding may indicate angina and ischemia in a child with an anomalous left coronary artery from the pulmonary artery. This is often confused with colic or reflux.

The presence of cyanosis should be determined. Cyanosis may be central or peripheral. Central cyanosis, which reflects true arterial desaturation, is characterized by blueness of the tongue and oral mucosa. Central cyanosis is most likely related to cardiac or respiratory disease. Children in shock also may appear cyanotic owing to venous stasis, right-to-left intrapulmonary shunting, or increased peripheral oxygen extraction. Acrocyanosis, or blueness of the hands and feet related to skin temperature, is normal. Similarly, blueness of the skin around the mouth or other parts of the face can often be attributed to alterations in skin blood flow or vasomotor instability, and should be considered to be a normal variant. Cyanosis may be more difficult to recognize in the anemic patient, because with decreased hemoglobin, similar levels of desaturation may not produce sufficient quantities of reduced hemoglobin (>5 g/%) to be clinically apparent.

If there has been observed cyanosis, it is important to distinguish between constant cyanosis and episodic cyanosis. In most forms of cyanotic congenital heart disease, cyanosis is constant. Constant cyanosis should suggest the presence of congenital heart disease with hypoxemia related to transposition physiology, inadequate pulmonary blood flow, or intracardiac mixing. Episodic cyanosis may be due to hypoxemia

related to hypercyanotic episodes from tetralogy of Fallot physiology (see Chapter 43). This can occur in tetralogy of Fallot, in some patients with double-outlet right ventricle, or in patients who have subpulmonic stenosis associated with a univentricular circulation.

Differential cyanosis of the upper and lower body in a newborn, although much less common, can also be an important finding. Lower body cyanosis with a pink upper body suggests right-to-left shunting at the level of the ductus arteriosus, seen in patients with persistent pulmonary hypertension of the newborn. Upper body cyanosis with pink lower extremities may indicate transposition of the great arteries with an aortic arch obstruction. In this circumstance, the lower body is perfused by the reversing ductus arteriosus that carries pulmonary venous blood via the left ventricle to the pulmonary artery.

The parent or caregiver's observation of the infant's breathing patterns should be documented. Unlabored ("happy") tachypnea often accompanies cyanotic heart disease, whereas increased work of breathing and sometimes grunting are associated with left-sided obstructive lesions or respiratory illness. Grunting with closure of the glottis provides positive end-expiratory pressure and is seen in infants who have pulmonary edema. Parents may also observe intercostal or subcostal retractions when the child is undressed. If the infant has been symptomatic from birth, some first-time parents may not recognize mild respiratory symptoms such as tachypnea.

Finally, newborns and infants who have heart diseases may have diaphoresis. This can occur during feedings or during sleep. Diaphoresis in this circumstance generally indicates activation of the sympathetic nervous system in patients who have low cardiac output.

The time at which signs and symptoms of heart disease begin may be a clue to the type of cardiac lesion. Commonly, murmurs detected early in the neonatal period originate from atrioventricular valve regurgitation or semilunar valve stenosis. Most newborns with acyanotic congenital heart disease are asymptomatic at birth. As the transition from fetal to postnatal circulation is completed, symptoms specific to the physiology of the defect become evident. For example, ductal-dependent left-sided obstructive lesions usually present in the first week of life as the ductus arteriosus closes, resulting in markedly decreased cardiac output and signs of shock. On the other hand, children with significant left-to-right shunt lesions typically are asymptomatic until 4 weeks of age or later, when pulmonary vascular resistance decreases to near adult levels and pulmonary overcirculation ensues. This may also be the first time a murmur is heard.

Toddlers and Preschoolers

Toddlers and preschoolers, like infants, are generally unable to give the examiner a true subjective history, so again, history in this age group is largely observational. Symptoms may be somewhat nonspecific. Again, feeding and breathing symptoms should be sought. As children become more physically active, parents may observe inability of children in this age group to sustain physical activity. Parents can be questioned regarding comparisons of these patients to siblings and age-mates about sustaining play or physical activity. Growth and developmental history is also important at this age. As they approach school age, children can sometimes voice subjective complaints, but often this is simplified to what the parent concludes is chest discomfort.

Older Children and Adolescents

As childhood progresses through school age and adolescence, the primary historian should be the patient. The parents should be asked additional pertinent historical and observational

information. Adolescents should have the right to speak privately, especially about drug use, sexual behavior, and other personal matters. A clinician should not betray their confidentiality and should not divulge to others the information revealed in confidence.

Older children and adolescents can be questioned much like adults regarding cardiovascular symptoms. Recognize that children with congenital heart disease may be symptomatic from birth and therefore may not experience a change in symptoms, as would a previously healthy adult with acquired heart disease. Older children and adolescents should be specifically questioned about their ability to tolerate exercise and physical activity. This may include the ability to participate in recreational activity and sports, but should also include activities of daily living such as walking or stair climbing. Shortness of breath with activity should be noted. Cyanosis with physical activity may indicate persistence or new appearance of a cardiac right-to-left shunt.

In older patients, a sleep history should be sought. Older patients may have paroxysmal nocturnal dyspnea or orthopnea with congestive heart failure. One should inquire about the patient's comfort when lying supine in bed, and if they require sleeping with elevation of the head by more than one pillow. Nocturnal awakening and shortness of breath can occur in heart failure with postural redistribution of edema fluid, particularly if there is pulmonary vein or mitral stenosis.

Palpitations are a common complaint in older children, and it is most helpful to have the subjective description of the events by the patient. The patient may describe transient or sustained sensation of an abnormal heartbeat, ranging from the sensations of the heart "skipping a beat" to the sensation of the heart beating hard or fast. The details of the symptoms should be carefully teased out to determine the circumstances in which they occur (e.g., rest vs. exercise), the frequency and duration of the complaint, and any associated symptoms such as fatigue, shortness of breath, or chest pain. It is often helpful to ask the parent about the appearance of the patient during these symptoms, specifically asking about pallor, breathing, and diaphoresis.

Chest pain at rest is a common complaint in adolescents and is generally noncardiac in nature. Again, in this circumstance, a subjective history is most helpful. The examiner should inquire about the nature of the pain, as well as its location, and duration. The examiner should ask the patient whether the pain is affected by breathing movements, cough, or arm and shoulder movements. Any other exacerbating or alleviating maneuvers should be sought. Chest pain with exercise should be questioned. Although chest pain with exercise is commonly associated with adult coronary disease, it is uncommonly associated with congenital heart disease. Exercise-induced chest pain may be found in patients with diseases resulting in significant left ventricular hypertrophy, congenital coronary artery abnormalities, or coronary abnormalities associated with Kawasaki syndrome, or can be due to noncardiac conditions such as exercise-induced bronchospasm.

Syncope is another symptom that is a frequent reason for Cardiology referral and may be due to a cardiac cause. When a patient presents with syncope as a complaint, the circumstances of the event and presyncopal symptoms are of greatest importance. Patients should be asked to describe where they were, what they were doing, and how they felt at the time of the event. Most postural syncope will occur when the patient is upright, generally standing. Often it occurs in a warm environment after a period of prolonged standing, but may also occur in some upon standing quickly from a sitting or supine position or while standing after a period of intense exercise. Dizziness or light-headedness, visual changes, feeling hot, or nausea often precede postural syncope. The examiner should inquire about presence of these presyncopal symptoms at other times when the patient has not lost consciousness. Additional

information that may be helpful includes the patient's daily intake of fluids and caffeine. Syncope without prodrome should be considered more significant for the possibility of a sudden severe arrhythmia.

Some patients may complain about edema, or swelling, although it is less commonly related to congenital heart disease in children and adolescents. The location of this edema is dependent upon the predominant posture of the individual. Patients who are upright much of the time may complain of swelling of their feet and ankles or of shoes that are tight at the end of the day. Younger patients who are supine much of the time may have sacral edema or puffiness of the face and eyelids.

Past Medical and Surgical History

The past medical history should include documentation of significant illnesses, previous hospitalization, previous operations, immunization status, and symptoms of poor growth as an infant. A detailed catalogue of previous cardiac and cardiothoracic procedures should be documented, including catheterizations, catheter interventions, and cardiac surgeries. The examiner should ask about the presence of other congenital anomalies and syndromes that may be associated with heart disease. Other illnesses and chronic conditions, immunization history, and allergies should be queried and documented.

Prenatal and Birth History

When evaluating a newborn for the first time, it is important to obtain details about the pregnancy. Details of the maternal health during pregnancy should be obtained, including maternal illnesses, medications, toxic exposures, and pregnancy-related complications. The infant of a mother with gestational diabetes, for example, has an increased risk of cardiac defects. Similarly, the relationship between maternal lupus and congenital heart block is well recognized. Maternal exposure to teratogens associated with cardiac defects (Table 5.1) should be part of the prenatal history (see Chapters 25 and 27). Smoking during pregnancy has been linked to small-for-gestational-age newborns but not specific cardiac defects. Congenital infections may lead to specific types of cardiac diseases. One example is rubella, which has been associated with patent ductus arteriosus and pathologic peripheral pulmonary stenosis. The use of illicit drugs may indicate an increased risk for human immunodeficiency virus infection, which has been associated with infantile cardiomyopathy. The age of the mother is important to determine her risk for offspring with chromosomal abnormalities such as trisomy 21. Complications such as toxemia, birth asphyxia, fetal distress, and low birth weight

may result in perinatal insult to the myocardium, leading to a generalized cardiomyopathy. The gestational age and birth history, including perinatal monitoring, method of delivery, and infant's Apgar scores, should be noted, and cyanosis, color, and perfusion status should be assessed.

Family History

A family history of relatives, especially siblings, born with heart defects indicates a higher than normal risk of congenital heart defects. For a couple that has already had a child with a left-sided obstructive lesion (i.e., hypoplastic left heart syndrome), the risk of congenital heart defects in subsequent children is increased. In most centers, a history of siblings with significant congenital heart lesions would prompt a referral to a pediatric cardiologist for a detailed fetal echocardiogram. A complete family history also should include the presence or absence of syndromes associated with congenital heart disease such as Marfan syndrome, Holt-Oram syndrome, long QT syndrome, and idiopathic sudden death. A positive family history for these diseases may warrant screening of other family members.

In the family history, one should identify the presence of premature myocardial infarction and hypercholesterolemia that may prompt cholesterol screening. The presence of congenital heart diseases in family members, and valve abnormalities such as bicuspid aortic valve should be determined. Heritable conditions such as hypertrophic cardiomyopathy should be specifically questioned. As in the infant, a family history of idiopathic sudden death in a close relative should prompt careful evaluation of the patient's QTc interval on a surface electrocardiogram.

Review of Systems, Social History

A review of systems and social history should include specific information regarding the patient's eating and exercise habits. School performance and sports participation should be assessed. A careful respiratory review of systems should be obtained. The clinician should make a private interview available to the adolescent. A history of tobacco and illicit drug use can then be determined. A discussion of personal habits gives the examiner an opportunity to advise about risk factors for coronary artery disease. This information is pertinent to the cardiac evaluation and aids in building the patient-physician relationship.

PHYSICAL EXAMINATION

Preparation and Strategy

We will now discuss the parts of the cardiac physical examination, including assessment of vital signs, inspection, palpation, percussion, and auscultation. Before the clinician proceeds with the examination, the patient should undress. The child may be covered with a blanket or wear a medical examination gown. The privacy and modesty of older children and adolescents must be respected. A staff member chaperone should be present during the examination of a patient of the opposite sex. Every child is different, so each examination must be individualized to be successful. The examiner must wash his or her hands or use sanitizing hand gel while being observed by the patient and parents doing so.

For the physician to perform a successful examination, the patient must be quiet and cooperative. This requires tact, patience, and innovation on the part of the examiner. If the infant is happiest in the mother's lap, then he or she should

TABLE 5.1 Common Teratogens and Their Associated Cardiac Defects

Teratogen	Cardiac Defect
Alcohol	ASD, VSD
Lithium	Ebstein's anomaly
Retinoic acid	Conotruncal abnormalities
Valproic acid	ASD, VSD, AS, PA/IVS, CoA

AS, aortic valve stenosis; ASD, atrial septal defect; CoA, coarctation of the aorta; PA/IVS, pulmonary atresia with intact ventricular septum; VSD, ventricular septal defect.

be allowed to stay there. The mother should feed or play with the child during inspection or palpation. The order of the examination can be adjusted based on cooperation to obtain the most information. For example, if the child is asleep, auscultation should be performed before palpation. In anxious toddlers and infants, often it is useful to auscultate before palpating, and any supine examination should be left for last. Toddlers can be examined through a combination of distraction and play. Older children can be approached in a more traditional “head-to-toe” approach used in adult patients.

The clinician should develop a routine (and stay with it) for listening to heart sounds so that each portion of the cardiac cycle is examined at several locations. At each location, it is important to focus on one sound or one interval at a time, in a systematic and consistent way. Most examiners start at the apex and work to the left lower and left upper sternal borders, then right upper sternal border. The clinician should be sure to auscultate the left subclavicular area, both axillae, the liver, the head, and the back. At each location, one must listen to the first heart sound, throughout systole, the second heart sound, and throughout diastole.

Equipment

There are several choices in stethoscope design, and choice of the best stethoscope is personal. Some advocate single tubing, whereas others prefer double-tubed devices. Some of the newer digital stethoscopes are quite useful, but may not accurately reproduce heart sounds as heard with an unamplified stethoscope. Whichever the instrument, the tubing must be intact, relatively short, and of sufficient bore. The earpieces must fit comfortably into the examiner's ears, and should be chosen to completely seal in the examiner's ears to reduce interference from ambient noise. Chest pieces vary in size. Larger diaphragms on adult stethoscopes may make localization of heart sounds more difficult, but is it possible to use a larger diaphragm by placing only a portion of the diaphragm on the chest wall. Chest pieces with a diaphragm and bell are essential to evaluate both high- and low-frequency sounds, respectively. In infants and small children, it is possible to hear high-frequency sounds by pressing on the bell, thereby creating a diaphragm with the skin. The examiner should become accustomed to his or her personal stethoscope and how it transmits heart and lung sounds.

Different types of manometers have been developed for blood pressure measurement. Although many hospitals are phasing out mercury manometers, they have been the most accurate tools for blood pressure measurement. Aneroid sphygmomanometers are the next most reliable, and are more commonly available. Although automated instrument (such as Dinamap) pressures are easy to obtain, these measurements are reliable only in quiet cooperative patients, and diastolic pressures are often unreliable. It is best to develop the skill of obtaining manual blood pressure for greatest reliability. A range of blood pressure cuffs of different sizes should be available so that infants through adults can be assessed.

A pulse oximeter has become a standard piece of equipment for noninvasive screening of a patient's oxygen saturation using photoplethysmography. There are several varieties of these devices from larger units to portable devices that clip on a fingertip. These devices should be kept in a well-maintained state and calibrated per manufacturer's recommendations.

Vital Sign Assessment

Heart rate, respiratory rate, and blood pressure are vital to a complete cardiac examination. They should be assessed at each visit.

Heart Rate and Respiratory Rate

The importance of changes in heart rate and respiratory rate are noted throughout this chapter. Often, changes in heart rate and respiratory rate are the first harbingers of myocardial dysfunction, pulmonary congestion, or arrhythmia, even before changes in blood pressure occur. Respiratory rate should be counted with the patient unaware that it is being done, and preferably while sleeping in infants. Postural changes in heart rate and blood pressure should be determined in patients with postural dizziness or syncope.

Blood Pressure Measurement

On the initial visit, blood pressures should be measured in both upper extremities and at least one lower extremity. The standard technique for measuring blood pressure should be used. First, the length of the bladder of the cuff should be 80% of the circumference of the limb, and the width of the cuff should cover at least two-thirds of the length of the extremity. If only the arm pressure is to be measured, the patient should be sitting. Finally, to obtain an accurate measurement, the cuff should be deflated slowly. Care should be taken to not compress the artery with the head of the stethoscope. Listening to the brachial or popliteal arteries yields the Korotkoff sounds that are used; first and fifth are now the standard. For comparison between upper and lower extremities, it is best to obtain both while the patient is supine. If the sounds cannot be heard, systolic pressure can be obtained by palpating the first pulsation of an artery distal to the cuff or by using a handheld Doppler probe over the distal artery as the cuff is deflated. Another alternative, especially helpful in uncooperative infants, is using the flush technique. This is done by manually blanching the hand or foot, inflating the blood pressure cuff, releasing the hand or foot, and slowly deflating the cuff until intense redness is seen in the previously pale extremity, estimating mean arterial pressure. Serial upper and lower body blood pressure measurements are important for following patients with coarctation of the aorta and other aortic arch anomalies.

Pulse Oximetry Screening

Pulse oximeter saturation measurement has become commonplace and has often become considered to be a fifth vital sign. It has been suggested that in newborn infants, early mild desaturation detected by screening pulse oximetry may allow earlier detection of congenital heart diseases (1), potentially leading to earlier treatment and decreased morbidity and mortality from significant congenital heart disease. It has been suggested that spot check of pulse oximeter saturation be performed in every newborn after 24 hours of life prior to hospital discharge, with 95% accepted as lower limit of normal. If a newborn fails to maintain oxygen saturation >95%, further screening would be planned. Currently, insufficient data are available to determine if this is cost-effective or if it should become standard of care in newborns. Despite the lack of such evidence, at least one state has passed legislation mandating newborn screening by pulse oximetry at the time of this writing, and several other states are considering mandating this screening. There has been a recent statement by the American Heart Association and American Academy of Pediatrics calling for future studies about screening by pulse oximeter saturation (1). Pulse oximetry is also used as a tool to follow the degree of cyanosis in patients known to have cyanotic heart diseases, and is followed serially at visits. Serial measurement of oxygen saturation in patients with acyanotic heart diseases is not necessary.

Growth Parameters

Height, weight, and head circumference should be measured in all patients, and serially tracked and plotted on growth charts at subsequent visits. Patients who have heart disease may have difficulty with weight gain or linear growth. Generally, head circumference is spared in all but the sickest patients. Newborns and young infants should establish which percentile curve that their growth parameters will follow. Falling consistently through percentiles or a plateau in growth of any of the parameters should be considered significant. After repair of a hemodynamically significant heart problem, infants often have a reassuring period of “catch-up” growth.

General Appearance

The physical examination actually starts at first contact, as soon as the room is entered. The examiner should take advantage of the time while interviewing the parent to observe the child. Each patient should be inspected for general appearance, nutritional status, dysmorphic features, color, and comfort. A thorough inspection often will clue the examiner to the cause and severity of an illness. The child's general appearance and comfort should be noted. Is the child fussy or playful? Is he or she well nourished? Are dysmorphic features or chromosomal abnormalities present? As discussed elsewhere in the text, specific cardiac lesions will accompany specific syndromes. The child's breathing pattern should be observed. Patients with severe heart failure, pulmonary edema, or pericardial restriction (tamponade, constrictive pericarditis) are more comfortable sitting up. Forcing such a patient into the supine position may result in respiratory failure. Patients should be allowed to determine the position in which they are most comfortable. The child's activity level, including feeding in infants, may be observed. In the infant, feeding constitutes exercise, which may elicit increased work of breathing, tachypnea, or diaphoresis.

Cyanosis and Clubbing

The child's color (i.e., pink, cyanotic, pale) should be noted. True cyanosis requires desaturation of 5 g% of hemoglobin and is difficult to detect unless the arterial saturation is $\leq 85\%$ in a child with normal hemoglobin levels. The best indicator of arterial desaturation is central cyanosis of the gums and tongue. The oral mucosa has a rich vascular supply and is free of pigmentation. Acrocyanosis that occurs in a cold environment or after bathing nearly always is a normal finding and is not true cyanosis. In the older child, long-standing cyanosis is usually accompanied by digital clubbing. The loss of the angle between the nail and the cuticle area is consistent and is often the earliest finding of clubbing. Cyanosis also results from respiratory disease or central nervous system disorders. During initial screening of infants, or if cyanosis is suspected, pulse oximetry should be obtained. In newborns with severe desaturation on oximetry, obtaining arterial blood gas analysis provides additional information about the degree of hypoxemia and if there is evidence of hypercarbia or acidemia.

Breathing Pattern

Resting breathing patterns can offer information regarding the patient's hemodynamic state. If the infant has central cyanosis, it is usually accompanied by a nonlabored tachypnea that results from hypoxic respiratory drive. Grunting is a physiologic means of producing positive end-expiratory pressure and often accompanies pulmonary edema. Nasal flaring and intercostal and subcostal retractions may be present.

If the infant is severely distressed, the head will bob with respiratory effort.

Neck Veins

Neck vein distention suggests impaired right ventricular filling. It may not be apparent in infants and toddlers because of their relatively short neck and relatively increased subcutaneous tissue. Neck vein distension is best observed with the patient positioned 30 degrees upright. Measurement of the height of neck vein distension above the manubrium can be used to quantify central venous pressure. Cannon A waves may be seen in patients with atrial contraction against a closed tricuspid valve. Regular cannon A waves can be found in patients with supraventricular tachycardia or atrial flutter. Irregular cannon A waves can indicate complete heart block.

Bobbing of the head may be seen in patients with significant aortic regurgitation. This is caused by increased carotid arterial pulsations striking the angles of the mandibles. The patient appears to be nodding “yes.” Patients with significant tricuspid regurgitation will exhibit lateral head movement. This occurs when regurgitant blood in the superior vena cava strikes the right mandibular angle. The patient appears to be nodding “no.”

Respiratory Examination

A careful respiratory system examination is important in assessing the cardiovascular system, as many heart diseases cause abnormalities in lung findings. This should include observation, percussion of the lung fields over the back while upright, and auscultation. Observation should include the presence of retractions, use of accessory muscles of respiration, and symmetry of chest wall motion with breathing, as discussed above. Patients who have asymmetric chest wall motion in the postoperative period should be evaluated for diaphragmatic paralysis from phrenic nerve injury. Percussion is a sensitive method for detecting pleural effusions postoperatively or in patients with heart failure. Auscultation of the breath sounds may reveal rales or crackles, wheezing, or rhonchi. Wheezing is of particular interest, as it is the most common pulmonary auscultatory finding in infants and toddlers with congestive heart failure due to either overcirculation or cardiomyopathy. In patients who present with a first episode of wheezing, heart disease should be considered as a potential cause. Stridor may be present in patients who have vascular rings or slings causing airway compression, or in patients who have absent pulmonary valve with associated severe pulmonary artery dilation.

Unexpected changes in the respiratory examination after surgery may be of significant importance. Most infants with appropriate palliation or surgical treatment of their heart disease will have fewer symptoms and findings on a respiratory examination. Raspy breathing or stridor in a postoperative patient should trigger investigation of the vocal cords that may be injured from direct trauma from endotracheal intubation, or paralyzed from injury to the recurrent pharyngeal nerve. Asymmetric chest wall movement again may indicate diaphragmatic hemiparesis due to phrenic nerve injury.

Cardiovascular Examination

There are three parts to a complete cardiovascular system examination. These include observation/inspection, palpation, and auscultation. Percussion is of little value for assessment of heart size and is not commonly performed to evaluate the heart.

OBSERVATION/INSPECTION

In addition to the general inspection described above, there can be observed findings that are specific to the cardiovascular system. Inspection of the chest wall may reveal chest wall surgical scars that suggest particular lesions. A right thoracotomy is used for placement of a right Blalock-Thomas-Taussig shunt, atrial septal defect repair, or mitral valve surgery. A midline sternotomy is used for most heart operations, especially if cardiopulmonary bypass is used. A left thoracotomy is used for patent ductus ligation, coarctation repair, or placement of a left Blalock-Thomas-Taussig shunt.

The clinician should inspect the chest for asymmetry or pulsatility. The transverse aorta sits under the suprasternal notch. Pulsations of the suprasternal notch may be visible in the presence of significant aortic runoff lesions such as aortic regurgitation. A left parasternal precordial bulge often is noted in patients with right ventricular volume overload (i.e., atrial septal defect). Examining a patient for a precordial bulge is best done with the patient supine, shoulders square on the examination table, with the examiner bending and looking tangentially across the chest. Because the dilated right ventricle is below the left precordium, the developing cartilaginous rib cage will expand to accommodate the structure. As the ribs ossify, the left precordial bulge remains. With the patient supine and the examiner at the feet of the patient, the point of maximal impulse can sometimes be observed. It is usually located in the left fourth intercostal space in the midclavicular line. In dextrocardia, it is on the right. It is displaced downward and laterally with left ventricular volume overload. Left ventricular hypertrophy does not usually alter the location of the point of maximal impulse.

PALPATION

Palpation of peripheral pulses, the chest, the abdomen, and the back should be included in each cardiac examination. Palpation of the extremities (peripheral) to assess pulses and perfusion and of the precordium (central) to assess activity and thrills should be performed.

Peripheral Palpation, Pulses

Pulses should be assessed, noting regularity and quality of the pulsations. Pulse rate changes with the age of the patient. A fast pulse rate for age may indicate arrhythmia or congestive heart failure. A slow pulse rate usually reflects athletic conditioning; however, atrioventricular block or drug effect should be considered. Irregularity of pulse rate may indicate an arrhythmia. However, a change in pulse rate with respiration is normal (sinus arrhythmia).

It is important to palpate pulses simultaneously in the upper and lower extremities, specifically right brachial or radial and right femoral pulses. Bilateral brachial pulses should be palpated simultaneously as well. If there is a delay between the upper and lower extremity pulses or absence of femoral pulsations, coarctation of the aorta should be considered. Diminished pulses are ominous in children and may suggest cardiac failure or shock. Absent or weak pulses in the left arm may result from previous subclavian flap repair of a coarctation of the aorta or in the right arm from systemic-to-pulmonary artery shunts (i.e., classic Blalock-Thomas-Taussig shunt). Bounding pulses reflect aortic runoff as in aortic regurgitation, patent ductus arteriosus, or arteriovenous malformations.

Assessment of tissue perfusion includes determining the quality of the peripheral pulses, as well as skin temperature

and capillary refill. Peripheral pulses should be full and easily palpable, not thready. Skin temperature should be determined, as should transition of central to peripheral cutaneous temperature. Temperature is best assessed using the dorsal aspect of the fingers. Change in temperature from central to peripheral can be determined by running the backs of the fingers from proximal to distal on the upper or lower extremities. Patients who have cool peripheral extremities who are warm centrally may be volume depleted or have low cardiac output. Capillary refill time is the time required for blanching to disappear after manually pressing on an extremity, and should be 3 seconds or less. While testing capillary refill, the clinician should examine the extremities for abnormalities associated with congenital heart disease, such as clubbing, finger-like thumbs (Holt-Oram syndrome), webbing of the digits, or polydactyly.

Central Palpation, Chest Wall

The chest should be palpated for the point of maximal impulse, precordial activity, and thrills. The location of the point of maximal impulse suggests the ventricular dominance. The chest should be palpated with a fingertip to confirm its location. With left ventricular dominance, the point of maximal impulse is palpated at the left midclavicular line or apex. A point of maximal impulse located at the lower left sternal border or xiphoid process suggests right ventricular dominance. Patients with dextrocardia will have a point of maximal impulse on the right side of the chest. Occasionally, an impulse will have a double contour or heave in the presence of volume overload (i.e., mitral regurgitation). In the face of pressure overload, a well-localized, sharp rising impulse or tap may be detected.

Precordial activity should be assessed. A hyperactive precordium suggests heart disease with volume overload. Volume overload may result from a large left-to-right shunt (i.e., a large ventricular septal defect or patent ductus arteriosus) or severe valve regurgitation (i.e., aortic and mitral insufficiency). In addition, left precordial bulging often is noted in patients with significant right ventricular volume overload.

Thrills are vibrations detected distal to jet lesions that are transmitted to the chest wall. Left precordial thrills are best felt with the metacarpal heads of the hand while the examiner is positioned to the right of the supine patient. Gently placing a fingertip in the suprasternal notch in supine patients will allow detection of aortic pulsations and thrills in patients with aortic valve disease. A thrill also may be palpable over the carotid arteries. Thrills located over the right upper sternal border are aortic in origin and are felt in patients with aortic valve stenosis. Left upper sternal border thrills are pulmonic in origin and generally indicate pulmonary valve stenosis, or occasionally, patent ductus arteriosus. A thrill may be felt over the left lower sternal border due to the jet of a restrictive ventricular septal defect as it strikes the endocardial surface of the right ventricle and transmits to the chest wall. Stenotic right ventricle-to-pulmonary artery conduits may produce a thrill. These are usually felt along the left sternal border.

In patients with pulmonary hypertension and elevated pulmonary arterial diastolic pressure, the pulmonic valve closure (P2) is often palpable at the left upper sternal border.

Palpation of the chest wall is also an important assessment in patients who present with the complaint of chest pain. Palpation of the costal-chondral joints should be performed to elicit tenderness. The pectoralis muscles should be palpated to determine if they are tender from injury. Placing the hands on the sides and performing gentle pressure with the palms will flex the costal-chondral joints to determine if there is pain with movement. It may be of additional benefit to have the patient perform some pectoralis muscle exercise to try to

reproduce chest pain. This could include “bench press” of the examiner’s hands, or having the patient try to bring elbows together in front of the chest against resistance to try to reproduce the patient’s symptoms.

AUSCULTATION

“Sound is the organized movement of molecules caused by a vibrating body in some medium” (2). In the case of heart sounds and murmurs, the medium is blood. Vibrations are produced by the cessation or propulsion of blood within the heart that, in turn, create sound that then radiates through the thorax, across the skin, and ultimately to the examiner through a stethoscope. The ability to identify heart sounds and murmurs and relate them to other clinical findings is an essential step in the evaluation of heart disease.

Classical teaching of cardiac auscultation suggests listening to the four valve areas and left sternal border (3). However, many of the cardiac sounds associated with congenital heart disease are heard in places other than the classic valve areas or left precordium. Listening between the valve areas will yield findings of subtle cardiac abnormalities that may not be even audible in the classic auscultation areas. For example, murmurs from some small muscular ventricular septal defects can be very localized, and are often heard midway between the tricuspid and pulmonary areas, at the mid left sternal border. Murmurs caused by coronary fistulae may be best heard at the lower right sternal border. And in patients who have dextrocardia, the cardiac sounds may best be auscultated entirely over the right precordium. A careful survey of where sounds are best heard is prudent. In patients with normal cardiac position, the pattern of auscultation might best be a large figure of eight, with the lower portion at the cardiac apex, and the upper portion being at the right sternal border, encompassing all of the left sternal border and much of the right sternal border.

Heart Sounds

Vibration of the valve apparatus, myocardium, pericardium, blood, or chest wall have all been implicated in the production of heart sounds (4–7). The timing of the first heart sound corresponds to the closure of the tricuspid and mitral valves. The second heart sound corresponds to the closure of the aortic and pulmonary valves. It has been shown that these sounds are not produced by coaptation of the valve leaflets, but rather the sudden deceleration of blood flow following closure of the valves. In turn, deceleration and cessation of blood flow cause surrounding cardiac structures and tissue to vibrate, producing audible sound (8,9).

The first heart sound (S1) occurs with closure of the mitral and tricuspid valves. There are four components to the first heart sound, but only the second and third are audible to the human ear. The first heart sound is typically a discrete, single low-frequency sound heard best at the left lower sternal border. The first heart sound is usually single in infancy. With aging, splitting of the first heart sound often becomes apparent. As with the second sound, splitting of the first heart sound varies with respiration. The timing of a split first heart sound can be confused with an early systolic ejection click. Typically, heart sounds are low in frequency, and clicks higher in frequency, but occasionally the distinction is difficult.

The second heart sound (S2) has two components that coincide with aortic and pulmonary valve closure. The aortic component (A2) precedes the pulmonary component (P2) because left ventricular contraction ends slightly before right ventricular contraction. Ordinarily, P2 is softer than A2.

Elevated pulmonary arterial diastolic pressure, as seen with pulmonary vascular obstructive disease, will cause the pulmonic valve to close crisply and accentuate P2.

The second heart sound is best heard at the mid and upper left sternal border. In the immediate newborn period, the second sound may sound single. Beyond the first 1 to 2 days of life, splitting of the second heart sound with respiration is expected, with splitting during inspiration and superimposition of the aortic and pulmonary closure sounds during expiration.

Abnormal splitting of S2 is an important finding when diagnosing heart disease. The interval of the split can increase in circumstances that prolong right ventricular ejection, such as atrial septal defects, total anomalous pulmonary venous connection, pulmonary valve stenosis, and right bundle branch block. Narrow splitting of S2 occurs with early closure of the pulmonary valve (i.e., pulmonary hypertension) or delayed aortic valve closure (i.e., severe aortic valve stenosis). Paradoxical splitting can occur in severe aortic valve stenosis, where left ventricular ejection is prolonged. A single second heart sound is not normal, and may represent atresia of an arterial valve, transposition, or pulmonary hypertension. Any heart disease that shifts the pulmonary valve away from the chest wall, such as D-transposition of the great arteries, will cause the second heart sound to be single. When the pulmonary artery is not adjacent to the chest wall, the softer pulmonary closure often becomes inaudible to the stethoscope. The second heart sound often becomes single and loud during pulmonary hypertension, as the timing of pulmonary closure becomes earlier.

The third heart sound (S3) may be heard early in diastole with rapid filling. It is a low-frequency sound, best appreciated with the bell of the stethoscope at the apex or left lower sternal border. Early in diastole, rapid ventricular filling causes vibration of the cardiac structures, producing a third heart sound. Many older children will have a normal soft third heart sound heard as a dull, low-frequency, middiastolic thud at the apex. An apical S3 is frequently heard in normal children and competitive athletes. Third heart sounds in older children should be considered to be normal. If a third heart sound is heard in the context of tachycardia, it is more likely to be a pathologic gallop than a normal sound. Later in diastole, atrial contraction augments ventricular filling.

If the ventricle is resistant to further distention, as in cardiomyopathy, the poorly compliant myocardium will vibrate, producing a fourth heart sound. Audible fourth heart sounds (S4) are almost always pathologic and are often found in patients with congestive heart failure. It is a low-frequency sound heard at the end of diastole just before S1. It is associated with rapid filling of the ventricle during atrial contraction and is heard in congestive heart failure and conditions of decreased ventricular compliance (i.e., cardiomyopathy). Its presence, often in the context of tachycardia, may sound like a gallop. When a gallop rhythm is heard, it is often difficult to distinguish whether a third or fourth heart sound is present. This is often called a “summation gallop” as it may represent one or both of these sounds, S3 and S4.

Clicks

Ejection clicks occur soon after S1 and are associated with semilunar valve stenosis (i.e., aortic or pulmonary valve stenosis) or with dilated great arteries. Aortic valve clicks are heard at the apex or right upper sternal border, and do not vary with respiration. Pulmonary valve clicks are heard along the left sternal border and are louder with expiration. Clicks associated with dilation of the aorta or pulmonary arteries are best heard over the vessel, at the right and left upper sternal borders, respectively.

A midsystolic, apical click is heard in the diagnostic finding of mitral valve prolapse. A midsystolic click may be accompanied by a late systolic murmur. Standing after squatting may accentuate a mitral valve click or regurgitant murmur in patients with mitral valve prolapse.

Friction Rubs

Friction rubs are pericardial sounds caused by movement of pericardial surfaces against one another. Friction rubs sound like the sound made by squeezing a paper bag or plastic wrap, occur in sync with heart rate, and are most often heard over the cardiac apex. Friction rubs are frequently heard in the 24 to 48 hours after cardiac surgery, especially when indwelling mediastinal chest tubes are in place. Pericarditis or other pericardial disease can cause a friction rub, although with large pericardial effusions, friction rubs can disappear.

Other Heart Sounds

Bruits are murmur-like sounds that can be heard in places other than the precordium as the case with arteriovenous malformations. Arteriovenous malformations may be responsible for unexplained cardiomegaly. In those instances, the clinician should listen for a bruit over the fontanelle or liver. In severe aortic regurgitation, one should listen over the femoral arteries for “pistol shot” sounds. The lungs should be examined for wheezing, rales, or abnormal breath sounds.

Heart Murmurs

Heart murmurs are thought to be the auditory representations of turbulent flow within the heart or blood vessels that is transmitted through the vessels, mediastinum, and the chest wall to the skin. Turbulence is described as highly disturbed flow that produces random fluctuations of velocity and pressure within the blood and vibration of the surrounding tissue. Turbulence can be described by the physical characteristic of Reynolds number. “The Reynolds number is a dimensionless quantity often used to describe the characteristics of steady flow through straight tubes at which transition from laminar to turbulent flow would occur” (10). The Reynolds number is defined as

$$Re = [(density\ of\ fluid)(velocity) / (tube\ diameter)] / viscosity\ of\ fluid$$

Although the cardiovascular system varies from the steady state conditions noted above, the transition to turbulent blood flow is thought to typically occur at a Reynolds number >2,000. There is debate whether murmurs are a direct result of turbulence or a consequence of turbulence.

Turbulent blood flow produces vibrations of the surrounding vessel in several ways. Direct impact of a jet against cardiac structures is the easiest to comprehend. However, several other mechanisms of creating vibration have been suggested (10). Eddy currents, for example, are produced adjacent to high-velocity jets. Like ripples in a pond, they produce vibrations as they strike the vessel wall. Second, pressure is lower in a moving fluid compared with stationary fluid. Therefore, the higher pressure outside of the moving fluid pushes the vessel wall toward the lower pressure fluid. This is called the Bernoulli effect. Fluctuations in the intensity of the Bernoulli effect may cause vibration of the vessel wall. Last, high turbulent flow can cause cavitation or the forming of bubbles of vapor in a liquid. Theoretically, these bubbles cause vibrations as they strike the vessel wall.

Heart murmurs should be evaluated in terms of intensity, timing, location, transmission, and quality (i.e., harsh, vibratory, etc.).

Intensity

The intensity of a murmur is relatively easy to determine, but is somewhat subjective. The intensity of a murmur is graded from I to VI where

- Grade I. Barely audible and may require several cycles to detect
- Grade II. Soft, but easily audible
- Grade III. Moderately loud murmur without a thrill
- Grade IV. Loud murmur with a thrill
- Grade V. Loud murmur heard with the stethoscope barely off the chest
- Grade VI. Loud murmur heard without the stethoscope touching the chest

The intensity of a murmur may reflect the pressure difference between the heart chambers or vessels where the abnormality exists causing the murmur. For example, as the severity of the aortic or pulmonary valve stenosis progresses, the associated murmur may increase in intensity reflecting a larger valve gradient. As ventricular septal defects become more restrictive, the associated murmur may become louder, reflecting a greater pressure difference between the ventricles. Murmur intensity when grade III or less does not help to distinguish innocent from pathologic murmurs. Any murmur that is grade IV or louder should be considered to be abnormal.

Timing

Heart murmurs should be described based on their timing during the cardiac cycle (Fig. 5.1). The timing of heart murmurs can be broken down into systolic murmurs (ejection and S1 coincident), diastolic murmurs (early diastolic, middiastolic, and late diastolic/presystolic), and continuous murmurs.

SYSTOLIC MURMURS

Systolic murmurs can be classified further as ejection or S1 coincident, based on the onset of the murmur relative to S1.

Figure 5.1. Diagram outlining timing of heart murmurs. This figure demonstrates the classification of heart murmurs based on their timing during the cardiac cycle. (A) represents the timing of systolic ejection murmurs, (B) S1 coincident murmurs, (C) late systolic murmurs, (D) continuous murmurs of vascular origin, (E) continuous venous hum, (F) early diastolic murmurs, and (G) mid and late diastolic murmurs.

Ejection Murmurs

The onset of systolic ejection murmurs occurs a short time after S1. Murmurs of this timing are separated from S1 by the period of isovolumic contraction and occur during the ejection phase of systole, while the aortic and pulmonary valves are open (Fig. 5.1A). They may be long or short and usually have a crescendo-decrescendo quality. They should end prior to S2. Ejection murmurs are the result of either obstructed blood flow through a stenotic semilunar valve or excessive volume through a normal semilunar valve. They are heard best over the site of altered flow (i.e., aortic, right upper sternal border; pulmonary, left upper sternal border) and radiate in the direction of flow.

Ejection murmurs associated with obstructed blood flow are heard with semilunar valve stenosis, subvalvular or supravulvular aortic or pulmonary stenosis, branch pulmonary artery stenosis, and hypertrophic obstructive cardiomyopathy. Ejection murmurs caused by excessive volume through the pulmonary valve are heard in atrial septal defects, pulmonary valve regurgitation, and anomalous pulmonary venous drainage. Commonly, an ejection murmur through the pulmonary valve is detected during pregnancy because of increased circulating volume. Ejection murmurs caused by excessive volume through the aortic valve are heard with aortic regurgitation, patent ductus arteriosus, and systemic arteriovenous malformations. Ejection murmurs are also heard when viscosity is decreased, such as with anemia.

S1-Coincident Murmurs

S1-coincident murmurs start with S1, and often obscure S1 as a separate sound (Fig. 5.1B). They may last through much of systole and are sometimes referred to as holosystolic or pansystolic murmurs (Figs. 5.1B and 5.2). S1-coincident murmurs occur when blood flows from a high-pressure chamber to a low-pressure chamber during what should be an isovolumic period in early systole. They are associated with ventricular septal defect and mitral or tricuspid valve regurgitation. When associated with valve regurgitation, their location corresponds with the tricuspid (left lower sternal border) and mitral (apex) valves. In the case of a ventricular septal defect, an S1-coincident murmur is heard along the left sternal border and may radiate to the right. The frequency or pitch of a ventricular septal defect murmur is directly proportional to the pressure drop through the defect; the higher the frequency, the smaller the ventricular septal defect (11). Mitral and tricuspid regurgitation murmurs are typically higher frequency and “blowing” in quality, being best heard in their respective valve areas.

Late Systolic Murmurs

Murmurs from mitral valve regurgitation due to mitral valve prolapse can occur in late systole (Fig. 5.1C). Often these murmurs are preceded by a midsystolic click. Typically, these murmurs are heard at the cardiac apex in the mitral valve area and are blowing in quality.

DIASTOLIC MURMURS

Diastolic murmurs are differentiated based on the timing of their onset during diastole: early diastolic, middiastolic, and late systolic/presystolic.

Early Diastolic Murmurs

Early diastolic murmurs begin immediately after S2 and are decrescendo in intensity as the pressure difference between artery and ventricle decreases during diastole (Fig. 5.1F). They are the result of early diastolic backflow from the great artery into the heart through an incompetent semilunar valve.

Aortic regurgitation murmurs arise from the higher diastolic pressure in the aorta and are therefore high pitched. They are heard best with the diaphragm of the stethoscope at the left mid-sternal border and radiate toward the apex. As the diastolic pressure gradient decreases, the murmur decreases in intensity. Listening while the patient leans forward and exhales accentuates the aortic regurgitation murmur.

Pulmonary regurgitation murmurs are also heard in early diastole. They are medium-low pitched murmurs unless there is diastolic pulmonary hypertension, in which case they are higher pitched. They are heard from the left upper to midsternal border and radiate down the left sternal border.

Middiastolic Murmurs

Middiastolic murmurs occur during the rapid filling phase of diastole when blood crosses the atrioventricular valves (Fig. 5.1G). They are low-pitched, often rumbling noises and best heard with the bell of the stethoscope. Pathologic narrowing or thickening of the mitral or tricuspid valves (i.e., mitral and tricuspid stenosis) causes a middiastolic murmur. Excessive flow through a normal-sized atrioventricular valve is heard as a middiastolic rumble and is erroneously referred to as “relative stenosis.” If the valve is held partially closed by an aortic regurgitation jet, a middiastolic murmur results, called the Austin-Flint murmur.

Mitral valve stenosis, ventricular septal defect, patent ductus arteriosus, and mitral regurgitation cause mitral valve middiastolic murmurs that are heard at the apex. Tricuspid

Figure 5.2. Digital phonocardiographic image demonstrating the S1-coincident murmur of a ventricular septal defect. The scale on the left denotes frequency of sound. The color scale on the right depicts intensity of sound. The corresponding electrocardiogram is plotted below. Arrows correspond to S1 and S2. The color display between S1 and S2 represents the various frequencies and intensities of the murmur. (From Balster DA, Chan DP, Rowland DG, et al. Digital acoustic analysis of precordial innocent versus ventricular septal defect murmurs in children. *Am J Cardiol* 1997;79:1552–1555, with permission from Elsevier.)

valve stenosis, atrial septal defect, and anomalous pulmonary venous return cause tricuspid valve middiastolic murmurs that are heard along the left lower sternal border.

Late Diastolic Murmurs

Presystolic murmurs also are caused by flow through narrowed atrioventricular valves (Fig. 5.1G). They occur late in diastole as a result of atrial contraction pushing blood through the narrowed valve into the ventricle. The murmur will accentuate with atrial contraction and will be absent if the patient is in atrial fibrillation. They are low-frequency murmurs heard in true mitral and tricuspid valve stenosis. They are rare in children, due to the low prevalence of children with true atrioventricular valve stenosis.

CONTINUOUS MURMURS

Continuous murmurs begin in systole and continue into, and often, through diastole (Fig. 5.1D,E). These murmurs almost always are vascular in origin. They are caused by aortopulmonary (dependent) (i.e., patent ductus arteriosus, surgical aortopulmonary) shunts or arteriovenous (obligate) connections (atrioventricular fistula, coronary–cameral fistula), turbulent flow in arteries (coarctation, severe branch pulmonary artery stenosis), or turbulent flow through veins (venous hum).

The most common pathologic aortopulmonary continuous murmur is heard in patent ductus arteriosus. It is loudest in systole and softest during diastole, giving it a “machinery” characteristic. It is continuous because of the constant pressure gradient between the aorta and pulmonary arteries and increases during systole because of a larger pressure gradient. In patients with levocardia, it is best heard at the left infraclavicular area. A surgically placed aortopulmonary shunt murmur sounds similar to that of the patent ductus arteriosus.

Other continuous murmurs arising from arterial malformations include coronary artery fistulae, pulmonary arteriovenous fistulae, bronchial collateral vessels, and pulmonary vessels arising from a truncus arteriosus. Coronary artery fistulas may empty into the right atrium, right ventricle, left ventricle, or pulmonary artery. These continuous murmurs may be louder in diastole. The location of the murmur will differ with each abnormality; however, it will usually be located on the lower pressure side of the abnormal connection.

Continuous murmurs occasionally are heard in patients with peripheral pulmonary arterial stenosis in whom flow into distal vessels varies and in patients with coarctation of the aorta who have large collateral vessels. Patients who are surgically palliated with bilateral pulmonary artery bands often have continuous murmurs. Murmurs due to peripheral pulmonary arterial stenosis of any cause will radiate over the lung fields, and be heard in the axillae and over the back.

Venous murmurs can be benign, as in the venous hum. They usually are heard over the left or right upper chest and disappear with changes in head position or compression of the jugular vein, and are truly continuous (Fig. 5.1E). They are typically low in frequency, vary with respiration, and are best heard with the patient upright.

In obstructed forms of total anomalous pulmonary venous return, a soft, high-pitched continuous murmur may be heard over the site of obstruction. The site of the murmur is determined by the locus of drainage, for example, over the liver.

Dynamic Auscultation

Patients should be examined in several positions to assess positional changes in murmurs and other findings. At a minimum, patients who are able to sit independently should be examined while sitting and supine. Older children should also

be examined while standing, and sometimes while squatting. Adolescents, patients being screened for sports participation, and patients with collagen vascular disorders should be examined supine and upright, including squatting to standing (dynamic auscultation) to detect the click and murmur of mitral valve prolapse or the ejection murmur of hypertrophic cardiomyopathy. This maneuver first places increased afterload on the heart, enlarging the left ventricle. Then, with standing, the ventricle is relatively unloaded, allowing mitral valve prolapse or dynamic outflow obstruction to be more manifest to the examiner. The change in position from supine to sitting often makes an innocent Still murmur softer. Reclining a patient from sitting to supine should make an innocent venous hum disappear completely.

Abdominal Examination

The abdominal examination is important and often fraught with difficulty, especially in the infant. To conduct a thorough examination, it may be best to palpate the abdomen last. The clinician should remember to warm his or her hands before starting. Bending his or her knees so that the abdominal muscles relax may relax a child who is tense or ticklish. It is generally possible to palpate the deeper aspects of the abdomen and maintain pressure during inspiration. The size and texture of the liver and spleen should be assessed, palpating above the pelvic brim and working slowly upward until the liver edge or spleen tip is felt. With increased venous pressure, the liver will be enlarged and its capsule may be tender. Percussion is also important to determine the location of the upper margin of the liver to determine liver span. This is particularly useful if the lungs are hyperinflated. Hyperinflation pushes the liver below the costal margin, giving a false impression of liver enlargement. In this case, percussion is a more accurate method for assessing liver size. Percussion over the lower left ribs for displacement or absence of the stomach air bubble can help to define splenomegaly.

Back Examination

Patients with congenital heart disease, especially those with chronically enlarged hearts and connective tissue disorders, have a high incidence of scoliosis. Other diseases that have cardiac manifestations such as Marfan syndrome can be associated with scoliosis. Therefore, examination of the spine for the presence of scoliosis should be part of the cardiac physical.

INNOCENT MURMURS

Innocent murmurs are the sound of noisy blood flow coursing through a structurally normal heart. They are heard in 50% or more of children at some time or another, particularly at around 3 or 4 years of age. They are accentuated by increased cardiac output, as when a child is excited, anemic, or febrile. Auscultation with the ability to differentiate pathologic murmurs from benign murmurs is the method of choice for diagnosing innocent murmurs. In general, innocent murmurs are low in intensity, and low in frequency. They are generally not harsh in quality. Most innocent murmurs, with the exception of the venous hum, are systolic ejection in timing. Innocent murmurs are not associated with abnormalities in the palpation exam (displaced point of maximal impulse or pulse abnormalities) and are associated with normal heart sounds. The presence of a click should be a clue that an associated murmur is not innocent.

Still Murmur

The most common innocent systolic murmur of childhood is Still murmur. It has many descriptions, including innocent, vibratory, functional, normal, and physiologic murmur. It is a systolic ejection murmur heard loudest somewhere between the left lower sternal border and the apex. Described as having a vibratory, musical, or twanging string quality, its usual intensity is grade I to III/VI. It is a low-frequency murmur in the range of 150 Hz (12). The murmur is heard best with the patient supine. This murmur also varies significantly with respiration, becoming softer and less vibratory during inspiration. As with all innocent murmurs, the electrocardiogram and chest radiograph are normal. The exact cause of this innocent murmur has not been determined. Suggestions include relatively smaller aortic size resulting in increased velocity of blood through the aorta during ejection, left ventricular false tendons, exaggerated vibrations with ventricular contraction, and increased cardiac output (13–15). Whatever the cause, the heart is normal, and a detailed imaging evaluation is unnecessary for diagnosis.

Pulmonary Flow Murmur of Childhood

A second innocent systolic ejection murmur is the pulmonary flow murmur. Commonly detected in thin-chested adolescents between 8 and 14 years of age, it is heard maximally over the pulmonary area. Although it resembles the ejection murmur of pulmonary stenosis, it is not particularly harsh in quality, and not accompanied by a click or thrill. Its intensity is 1 to 3/6, and the second heart sound should have normal splitting with the P2 component sounding normal. This murmur is frequently heard in patients who have increased cardiac output from fever, anemia, or pregnancy. If this murmur is heard in the presence of fever, and is not present when afebrile, it may not require any further evaluation. If the murmur of pulmonary flow is present in a patient who is not in an increased output state, lesions of increased pulmonary flow, such as atrial septal defects, should be considered.

Pulmonary Flow Murmur of Infancy

Also referred to as a peripheral pulmonary flow (peripheral pulmonary stenosis) murmur, this murmur is commonly heard during the newborn period and early infancy, particularly in premature infants. It is an ejection murmur that radiates from the left upper sternal border over the lung fields to both axillae and the back. Theories of its origin include the relatively small size of the branch pulmonary arteries immediately after birth, as well as their angle of the takeoff from the main pulmonary artery during the newborn period (16,17). Whatever the cause, it usually disappears by 6 months of age. If the murmur persists past 6 months of age, structural abnormalities of

the pulmonary artery tree, or lesions that increase pulmonary blood flow such as atrial septal defect should be considered.

Venous Hum

The venous hum murmur, as discussed above, is the only innocent murmur that is not systolic ejection in its timing. This murmur is low frequency and truly incessant when the patient is upright. Typically, this is a low-frequency noise that sounds more like a motor running in the background. Generally, some variation in pitch and intensity occur with respiratory and cardiac cycles. This murmur will cease with maneuvers that occlude the neck veins, either by direct compression using a thumb, or by turning the patient's head to look over the contralateral shoulder. Gravity driven, this murmur should also completely disappear with the patient flat in a supine position.

Exercise Screening and Sports Participation

Julie A. Brothers ■ Paul Stephens, Jr. ■ Stephen M. Paridon

Over the last 30 years, there has been a significant increase in the rates of overweight and obesity in children in developed countries. Concurrently, there has been a decline in physical activity in children and adolescents. The reasons for these trends are multiple and include a shift to a high-fructose diet, increased fat and processed food consumption, and increased sedentary activity such as watching television and video gaming. The result is a young population at risk for an epidemic of hypertension, type II diabetes, and early atherosclerotic coronary disease (1,2). Recent data on obesity trends in children with congenital heart disease (CHD) indicate their incidence of obesity is similar to that of the general pediatric population. The risks for complications of obesity appear to be at least as great in this population as in the general population (3,4). Given these trends, there is an essential need to promote routine vigorous physical activity in both the general pediatric population and, in particular, the CHD population.

Balanced with the need to promote physical activity as an essential part of a healthy lifestyle is the need to keep children and adolescents safe from the risk of sudden cardiac death (SCD) during physical activity. Although SCD is very rare in the pediatric and young adult population, congenital cardiac defects, either myopathies or structural abnormalities, are the major causes of these events (5,6). SCD occurs very rarely in patients with known congenital cardiac disease. Much more commonly, it happens to those athletes not previously suspected of having cardiac abnormalities. There are few evidence-based recommendations for the screening of athletes for risks of SCD. Much controversy surrounds this topic. There are even fewer evidence-based data regarding the screening and participation for athletic activities for children and adolescents with known CHD. What information is available is restricted to adolescents and young adults, and, importantly, current recommendations are restricted to competitive sports. There is essentially no information on the safety or screening of preadolescents with CHD for physical activity. As well, there are almost no evidence-based guidelines for children and adolescents with CHD wanting to participate in leisure or recreational activities. Likewise, guidelines for activities of daily living especially for young adults with CHD are very limited.

The goal of this chapter is to discuss the current state of knowledge for athletic screening and participation in children with CHD. It broadly discusses the current recommendations regarding physical activity promotion in the pediatric, adolescent, and young adult populations. It also discusses the differences and various types of physical activity such as those of daily living, leisure sports, and organized competitive athletics. As well, differences in physiologic requirements of various athletic activities and their associated risks are discussed. The current methods and recommendations for screening for SCD during physical activity are reviewed. Controversies regarding the type and timing of screening are addressed. Finally, what is known about the ability to participate in and the risks of athletic activities for the individual groups of congenital cardiac

defects is discussed with emphasis on what is known about preathletic screening and recommendations for activities of daily living, leisure and recreational athletics, and participation in competitive sports.

PHYSICAL ACTIVITY AND EXERCISE

Physical performance during exercise depends on the individual's strength, endurance, and skill in performing a given athletic activity. These in turn may be influenced by a number of factors such as age, sex, height, weight, and especially cardiovascular conditioning. The ability to successfully and safely undertake a given athletic activity depends on the combination of these factors and the requirements of the activity.

All athletic activities can be roughly broken down into their "static" and "dynamic" components (7). The static component is the amount of maximal voluntary contraction (MVC) of the exercising muscles required to perform the activity. This is what is traditionally considered isometric activity or the muscles working against resistance. Examples of activities requiring high static forces are weight lifting and wrestling. The cardiovascular effects of isometric activity depend on the intensity of the activity (e.g., the percentage of MVC required) and the size and number of the muscle groups involved in the activity. Contraction of muscles during isometric activity results in an increase in peripheral vascular resistance (PVR) with a consequent rise in systolic, diastolic, and mean blood pressures. The degree of increase in these values depends on the size of the muscle group and the percentage of MVC achieved but may result in systolic blood pressures in excess of 300 mm Hg with heavy weight lifting. On the other hand, cardiac output and total body minute oxygen consumption (VO_2) are relatively unchanged by brief severe static activity (8–10).

The dynamic component of exercise can be thought of as the activity that results in muscle contraction and body movement. These activities are usually repetitive and against low resistance (7,9). This is what is thought of as isotonic activity. An example of a highly isotonic activity is long-distance running. The cardiovascular effects of high dynamic activity are quite different from static activity. The metabolic demands of the exercising muscle are much greater. The VO_2 may rise 10-fold or more from resting values with highly dynamic activity. To meet this oxygen demand, cardiac output may rise fivefold or more in well-conditioned athletes. Although systolic blood pressure rises as the cardiac output increases, vasodilation of the vascular bed of the exercising muscles results in a significant drop in PVR with highly dynamic exercise. Thus, dynamic exercise results primarily in a volume load being placed on the heart as opposed to the pressure load that results from highly static activity.

In truth, there are no pure "static" or "dynamic" activities, and all athletic activities are to some degree a combination of

Increasing Static Component ↑	III. High (>50% MVC)	Bobsledding/Luge*, Field events (throwing), Gymnastics*, Martial arts*, Sailing, Sport climbing, Water skiing*, Weight lifting*, Windsurfing*	Body building*, Downhill skiing*, Skateboarding*, Snowboarding*, Wrestling*	Boxing*, Canoeing/Kayaking Rowing Speed skating*, Triathlon Cycling*, Decathlon
	II. Moderate (20–50% MVC)	Archery, Auto racing*, Diving*, Equestrian*, Motorcycling	Football*, Field events (jumping), Figure skating*, Rodeoing*, Rugby*, Running (sprint) Surfing*, Synchronized swimming	Basketball*, Ice Hockey*, Cross-Country Skiing (skating technique), Lacrosse*, Running (middle distance), Swimming, Team handball
	I. Low (<20% MVC)	Billiards, Bowling, Cricket, Curling, Golf, Riflery	Baseball/Softball*, Fencing, Table tennis, Volleyball	Badminton, Cross- country Skiing (classic technique), Tennis, Race walking, Running (long distance), Field Hockey*, Soccer*, Racquetball, Squash, Orienteering
		A. Low (<40% Max O ₂)	B. Moderate (40–70% Max O ₂)	C. High (>70% Max O ₂)
		Increasing Dynamic Component →		

Figure 6.1. Classification of sports. This classification is based on peak static and dynamic components achieved during competition. It should be noted that higher values may be reached in training. The increasing dynamic component is defined in terms of the estimated percent of maximal oxygen consumption (Max VO₂) achieved and results in an increasing cardiac output. The increasing static component is related to the estimated percent of MVC reached and results in an increasing blood pressure load. The lowest total cardiovascular demands (cardiac output and blood pressure) are shown in green and the highest in red. Blue, yellow, and orange depict low moderate, moderate, and high moderate total cardiovascular demands, respectively. *denotes collision risk. (From Mitchell JH, Haskell W, Snell P. Task Force 8: classification of Sports. *J Am Coll Cardiol* 2005;45:1364–1367, with permission from Elsevier.)

both types. Figure 6.1 shows the relative amounts of static and dynamic forces required for various types of competitive sports that was published as part of the 36th Bethesda Conference on Competitive Sports Participation in Athletes with Heart Disease (7). Increasing dynamic activity requires a higher VO₂ while increasing static activity requires a higher percentage of MVC. There are sports such as rowing and cycling that require both high static and high dynamic components.

This figure has been widely published and used by clinicians to help to make recommendations for activities for their patients with heart disease. It is important to remember that the values for this table refer only to competitive sports in adolescents and adults. The contents of this table have little or no relevance to competitive sports participation in the preadolescent population. Much of preadolescent competitive sport training focuses on learning basic skills and coordination. Strength and endurance training have very little or no place in competitive sports at this age. Any parent will tell you that soccer played by a group of 7-year-olds bears almost no relationship to soccer being played by a group of 17-year-olds. Understanding these differences is crucial since it impacts directly on the ability of athletes with CHD in these age groups to successfully and safely participate in the athletic activity.

Types of Physical Activity

Physical activities can be divided into three broad types of activities: (a) activities of daily living, (b) leisure and recreational sports, and (c) competitive sports. All patients with CHD

participate in the first type of activity. Many also participate in the one or both of the latter two types. Understanding the differences between these types of activities is important to being able to assess the capabilities and safety of individuals with CHD to perform these activities.

Activities of Daily Living

“Activities of daily living” is an inclusive term that encompasses all the physical activities required by an individual as part of his or her routine daily tasks. These requirements will vary greatly depending on the age of the individual as well as many other unique circumstances. There have been attempts to quantify the amount of physical activity that occurs during typical activities of daily living among different ages of children, adolescents, and young adults both with and without CHD. These studies used various types of motion detectors as well as recall questionnaires. The results of these studies were mixed, but generally indicated that children and adolescents with CHD perform significantly less physical activity as part of their daily routine (11–13). This difference was most pronounced in boys with CHD compared to their healthy peers (12,13). It is also worth noting that most children tend to overestimate the amount of physical activity they perform (14,15).

The reasons for this difference in physical activity associated with daily living among children with CHD are not clear. There is at least some evidence that this is due to activity restrictions that have been imposed by physicians, parents, and in some cases by the children themselves (16). This has been seen even in children with relatively trivial cardiac conditions. The consequence of these restrictions may well be quite significant. Recent studies of obesity trends in children with CHD are alarming. Obesity in this population mirrors that of the general pediatric population and occurs even in populations with otherwise excellent cardiac repair and normal or near-normal exercise capacities (3,4,17). There is at least some evidence that the amount of obesity is related to daily amounts of physical activity.

Assessment of activities of daily living is even more important in the case of young adults with CHD. These activities will usually include those required for employment. The intensity of physical activity can obviously vary greatly from individual to individual depending on the nature of their employment. Although this may seem obvious, the little research available would suggest that this aspect of patient care is largely ignored by the patients and their physicians. Of concern is the finding that the most common reason patients do not seek information about appropriate level of physical activities is a mistaken belief that all activities are safe to perform (18).

Leisure and Recreational Sports

Leisure and recreational sports are physical activities that are engaged in without pressure to participate and are performed at the individual's desire and comfort level. In short, they are activities that are undertaken without formal coaching. This definition encompasses a broad category of activities. Although there may be no formal coaching, some of these activities have significant organization and structure. Intramural sports at the high school or college level may often fall into this category. Less structured activities such as playground “pick-up” games as well as physical activities that may be undertaken by an individual such as cycling or jogging would also fall under this category of leisure or recreational sports. A careful history of these activities is an important part of the assessment of a patient with CHD. Clearly, the intensity with which these leisure activities are performed may vary widely with the age and circumstances in which they are undertaken. This also highlights the importance of understanding the difference and

intensity of sports at a recreational as opposed to a competitive level. Intramural flag football has little in common with competitive high school football. For this reason, it does not make sense to use the information in Figure 6.1 on the intensity of this sport to determine if it is safe for a patient with CHD to play at an intramural level.

Competitive Sports

Competitive sports are those that are generally organized, coached, and played at high skill levels. They often, but not always, require high-intensity physical activity (see Fig. 6.1). The intensity with which an individual participates in competitive sports is influenced by their personal motivation as well as the outside influences of the coach, other team members, parents and other family members, and spectators. The end result is the potential for the individuals to push themselves to participate beyond the level they might otherwise choose to or which might be considered safe by their physician.

It is also important to remember that training is a significant part of competitive sports. The training for competitive sports may in many cases be of higher intensity than participation in the actual sport. For example, weight training and physical conditioning undertaken by high school athletes playing baseball may easily exceed the intensity of the activity they achieve in the actual game. When considering the safety of participation of an individual with CHD in a particular sport, the requirements of training must be considered equally with the sporting activity itself.

It is also important to remember, as stated earlier, that “competitive” does not necessarily mean the same thing for all ages. None of the factors that influence high levels of performance in adolescents and adults, such as coaching and spectators, are likely to have much of an effect on young children. Especially at early ages, children are very unlikely to perform beyond a level that they would otherwise choose to self-limit. As such, these “competitive” sports should be thought of more as activities to teach basic physical skills rather than true competitive athletics (19).

Promoting Physical Activities and Exercise in Patients with Congenital Heart Disease

Given the concerns of growing obesity and sedentary lifestyles in the population with CHD, what should the recommendations be for physical activity in this population? Regardless of age, in the vast majority of the population, the recommended level of 60 minutes of moderate to vigorous physical activities per day is probably appropriate. This level of activity corresponds to approximately 50% to 60% of maximal VO_2 or 70% of maximal heart rate (20). As will be discussed later in this chapter, this is a level of physical activity that is often achieved in recreational activity or in many cases through competitive sports and is both safe and desirable for many individuals with simple congenital heart defects. Often with minor CHD, minimal formal testing may be required prior to individuals undertaking this level of activity. In more complex defects and usually following an operative repair, more formal studies including electrocardiogram (ECG), echocardiogram, and exercise testing may be indicated. The need and the rationalization for these tests will be discussed for the individual defects.

In individuals with complex defects and residual cardiac dysfunction, studies from the adult heart failure literature suggest that they would still benefit from routine regular physical activity. However, these patients may need physical activity programs that are more specifically designed for their degree of cardiac fitness (21–23). In these circumstances,

formal exercise testing with assessment of VO_2 , work rate, and heart rate is very useful in generating an exercise prescription. This can be used to instruct the patient in the types and intensity of activities that are both safe and beneficial. These prescriptions are usually based on what is referred to as **FITT**-factors. **FITT** is an acronym for Frequency, Intensity, Time and Type. All four factors should be included when generating an exercise prescription and address both activities with primarily dynamic and static components to assure optimal physical conditioning (24). This type of activity classification is used throughout this chapter in making recommendations for activities in individual congenital cardiac defects.

PREPARTICIPATION SCREENING FOR UNDIAGNOSED CARDIAC CONDITIONS

Incidence of Sudden Cardiac Death

SCD in individuals younger than 35 years of age during or just after exercise is almost always attributable to structural or functional cardiac disease (25). In the United States, the most common cardiac causes of SCD are hypertrophic cardiomyopathy (HCM), commotio cordis, coronary artery anomalies, other cardiomyopathies, electrical abnormalities (e.g., long QT syndrome, catecholaminergic polymorphic ventricular tachycardia, Brugada syndrome), myocarditis, Marfan syndrome, aortic valve disease, atherosclerotic coronary artery disease (CAD), and others (25–28). Because there is no mandatory reporting system in the United States, the exact frequency of SCD is unknown. Published reports have relied on public media, catastrophic insurance claims, and electronic databases. From these, estimates of SCD range from 1:160,000 to 1:300,000 for competitive athletes aged 12 to 35 years (25,27,28). These may underestimate the true incidence of SCD since without mandatory reporting, it is likely that some cases are missed. Indeed, there are other studies that have reported a higher incidence of SCD in the United States, ranging from 1:9,000 in United States military recruits (29) to 1:67,000 in a retrospective survey of college athletes aged from 18 to 23 years (30–34). In the Veneto region of Italy, prior to implementing a national screening program, the incidence of SCD was 1:28,000 for competitive athletes aged from 12 to 35 years. This is based on a mandatory registry of SCD in the region (35).

Risk of SCD appears to differ based on gender, race, and activity. SCD occurs more often in males than females (26,27,36), which may be explained by the greater participation rates in males compared to females in competitive athletics. In the United States, African Americans are at greater risk than Caucasians for SCD (36). Participation in soccer and basketball carries the highest risk of SCD, but this may be explained by the popularity and higher participation rates in these sports compared to other activities (26).

Although debatable, most agree that regular training for athletic competition is associated with an increased risk of SCD in those athletes who have underlying occult cardiovascular disease compared to sedentary young individuals. In 2003, Corrado et al. reported the incidence of sudden death in the athletic and nonathletic young population (12 to 35 years) in the Veneto region of Italy. These authors demonstrated that participating in competitive sports increased the risk of sudden death in adolescents and young adults by 250%. They reported an incidence of sudden death of 2.3 (2.62 in the males and 1.07 in females) per 100,000 athletes per year from all causes and of 2.1 per 100,000 athletes per year from cardiovascular disease (5).

Purpose of Preparticipation Screening

Why do we perform preparticipation screening? Is the purpose to prevent SCD or is it to identify those children with cardiovascular abnormalities that may place them at increased risk for SCD? The answer appears to be the latter. The American Heart Association (AHA) states that preparticipation screening is the “systematic practice of medically evaluating large, general populations of athletes before participation in sports for the purpose of identifying (or raising suspicion of) abnormalities that could provoke disease progression or sudden death” (37) (Fig. 6.2). Similarly, according to the 36th Bethesda Conference Guidelines “the ultimate objective of pre-participation screening carried out in general populations of trained athletes is the recognition of “silent” cardiovascular abnormalities that can progress or cause sudden cardiac death” (38). The American Academy of Pediatrics recently published guidelines for preparticipation screening, with the goal to “uncover conditions that might require further investigation or treatment” that would hinder the health and safety of the athlete (39). Thus, it appears that the main goal of screening is to discover underlying cardiovascular disease that has the potential for SCD. Based on estimates from several studies using noninvasive testing, approximately 1 in 500 young athletes may have an underlying cardiac condition that places them at increased risk of SCD (35,37,40–43). Many cardiovascular conditions, once identified, can be treated to help reduce the risk of SCD. Treatment may include activity restriction, pharmacotherapy, electrophysiology studies and procedures, implantable cardioversion defibrillator placement, and in some cases, surgical repair.

Current Preparticipation Screening Recommendations

Both the AHA and the European Society of Cardiology (ESC) agree that preparticipation screening of young athletes is warranted; however, controversy exists between the U.S. and European recommendations on the inclusion of a 12-lead ECG as part of routine screening (37,44). The first consensus statement on preparticipation screening in the United States

was published by the AHA in 1996 and was reaffirmed in 2007 (37,45). This statement recommended a detailed personal and family history and physical examination (Fig. 6.2). A 12-lead ECG was not included. One of the major issues with this approach is that many athletes with a predisposition to SCD are asymptomatic, with normal histories and physical examinations. Often, the first sign of an underlying cardiovascular condition is SCD in up to 60% to 80% of these athletes (26,46,47). The limited value of history and physical examination alone was noted in a retrospective analysis of 115 high school and collegiate athletes who died suddenly. The authors found that cardiovascular abnormalities were suspected by standard history and physical examination screening in only 3% of the examined athletes and screening led to the accurate diagnosis in only one athlete (26). In the United Kingdom, prospective studies using history and physical examination were not efficacious in identifying those with underlying cardiovascular conditions associated with SCD (48).

The current recommendations from the ESC, endorsed by the International Olympic Committee (IOC) and several professional sports organizations, include a 12-lead ECG in addition to the screening history and physical examination (44,49). For over 25 years, Italy has evaluated several million athletes annually, under a state-subsidized screening program (44). The evaluation is performed by specially trained physicians who work in centers dedicated to preparticipation screening of athletes and is performed starting at age 12 to 14 years and repeated at least every 2 years (44). The protocol also incorporates guidelines for further investigations if any cardiovascular abnormality is found or suspected.

Benefits of Mandatory Preparticipation Electrocardiogram Screening

In the United States, the inclusion of additional noninvasive tests, such as the 12-lead ECG, to preparticipation screening of young athletes is highly debated (50–53). The European recommendations are based on several studies demonstrating increased sensitivity using ECG to detect occult cardiovascular pathology compared with history and physical examination alone (35,40–43).

Figure 6.2. The American Heart Association Pre-participation Screening of Competitive Athletes Recommendations (12-Elements) (Adapted from Maron BJ, Thompson PD, Puffer JC, et al. Cardiovascular pre-participation screening of competitive athletes. A statement for health professionals from the Sudden Death Committee (clinical cardiology) and Congenital Cardiac Defects Committee (cardiovascular disease in the young), American Heart Association. *Circulation* 1996;94:850–856.).

^aIn middle and high school athletes, parental verification of medical history is recommended.

^bNot vasovagal (neurocardiogenic); particularly concerning if related to exercise.

^cAuscultation should be done both while supine and standing, or with Valsalva maneuver, in order to identify murmurs of dynamic left ventricular outflow tract obstruction.

Medical History^a

- Chest pain on exertion
- Chest pain with exercise
- Syncope/near syncope that is unexplained^b
- Unexplained or excessive dyspnea/fatigue with exertion
- Prior heart murmur
- Elevated systemic blood pressure

Family History

- Premature death < 50 years from heart disease, sudden or otherwise, ≥ 1 relative
- Disability from heart disease in a close relative < 50 years of age
- Knowledge of certain cardiac conditions in relatives: hypertrophic or dilated cardiomyopathy, long QT syndrome or other ion channelopathies, Marfan syndrome, or clinically significant arrhythmias

Physical Examination

- Heart murmur^c
- Evaluation of femoral pulses, to exclude aortic coarctation
- Physical characteristics of Marfan syndrome
- Brachial artery blood pressure (sitting, in both arms)

Genetic cardiomyopathies are the most common cause of SCD in young athletes. In the United States, HCM is most common while in Italy, arrhythmogenic right ventricular cardiomyopathy (ARVC) predominates (25,35). While cardiomyopathy is definitively diagnosed with cardiac imaging, ECG screening can detect approximately 95% of those with HCM and 80% with ARVC (54,55). Corrado et al. (56) reported on a 17-year experience of preparticipation screening that included ECG in the Veneto region of Italy. During 1979 to 1996, a consecutive series of 33,735 young athletes was evaluated. Of these athletes, 1,058 were disqualified for medical reasons and 621 (1.8%) because of the recognition of clinically relevant cardiovascular abnormalities. Among the athletes screened, 22 (0.07%) showed both clinical and echocardiographic evidence of HCM, which accounted for 3.5% of the cardiovascular causes for disqualification. The authors showed that, when compared to history and physical examination alone, ECG had 77% greater power to identify HCM. Similarly, a population-based study of 4,111 young adult athletes in the United States using ECG found a diagnosis of HCM in 7 (0.17%) by echocardiography, 5 of whom had an abnormal ECG (71%) (57). The Italian ECG-based preparticipation screening model has also been shown to have a high negative predictive value (99.98%) in excluding HCM in those young athletes who have normal ECG (58). This model was found to be effective in reducing rates of SCD from ARVC with a significant decline (84%) in incidence rates from the prescreening to the postimplementation of screening era (35).

In 2006, Corrado et al. reported on a prospective observational analysis of 42,386 young athletes, evaluating the rate of SCD in those undergoing screening to those nonathletes who did not have preparticipation screening over more than 25 years. Results were compared for the era prior to use of ECG for preparticipation screening to the 25-year era with ECG screening. There was a 90% reduction in mortality in young athletes since the beginning of the screening period. The rate of SCD in nonathletes remained constant over the same period. The reduction appeared to be due to fewer cases of SCD from cardiomyopathies (mainly ARVC) and to increased identification of cardiomyopathies at time of screening (35). Recently, Wilson et al. evaluated 1,074 junior athletes (ages 10 to 27) and 1,646 physically active schoolchildren (age 14 to 20) in the United Kingdom using personal and family history, physical examination, and resting ECG. Nine athletes (0.3%) were found to have cardiovascular abnormalities predisposing them to SCD. All were detected by ECG alone as none had symptoms or family history of SCD (59).

Concerns about Mandatory Preparticipation Electrocardiogram Screening

In the United States, obstacles exist to implementation of an obligatory national screening of competitive athletes using ECG. Some of these obstacles include the large population of athletes to be screened (10 to 12 million), diverse ethnic and racial population in the United States, and the recognition that it is impossible to absolutely eliminate the risks associated with competitive sports (5).

Another main concern regarding the use of ECG during preparticipation screening relates to the high false-positive rate. In the study by Corrado et al. (35), a 7% false-positive rate with 2% of athletes being disqualified was reported; only 0.2% of athletes were ultimately disqualified for potentially fatal cardiac conditions. This raises concerns regarding unnecessary further investigations and/or false disqualification of an athlete who is not actually at increased risk for SCD (60). Several recent studies have been published utilizing strict ECG criteria when screening athletes to take into account

the physiologic adaptation to heart structure and function in athletes ("athlete's heart") affecting the interpretation of ECGs. In the study by Wilson et al., the authors reported a false-positive rate of 3.7% using history, physical examination, and ECG with 1.9% false positives due to ECG alone (59). Hevia et al. (61) evaluated 1,220 amateur athletes in Spain using history, physical examination, and 12-lead ECG and found 6.14% of ECGs were abnormal with 2 cases of HCM diagnosed by ECG. There were 15 cases with positive criteria on history or physical examination, but none were found to have cardiac disease by echocardiography (1.2% false-positive rate). In 2007, Pelliccia et al. (62) described ECG abnormalities on 32,652 amateur athletes (median age 17 years) undergoing preparticipation screening in Italy and found 12% had abnormalities but only 40% of those abnormalities (4.8% of the population) required further diagnostic testing.

Two recent studies have further called into question the usefulness of 12-lead ECG as part of preparticipation screening of athletes. Maron et al. (63) compared sudden death rates in Minnesota, where ECG is not part of routine screening, to that of the Veneto region of Italy, where ECG screening is mandatory. Over a 23-year period, the SCD rate of high school athletes in Minnesota was 1.06 per 100,000 person-years and 1.87 per 100,000 person-years in Italy. These data demonstrated that the SCD rate was low in both locations and does not support a reduced mortality rate due to use of ECG in preparticipation screening. As well, Steinvil et al. (64) reported on the sudden death rate prior to and after mandatory preparticipation screening program in Israel. This screening consisted of medical history, physical examination, ECG, and exercise stress testing. The authors found no significant difference between the average yearly incidences of SCD (2.54 per 100,000 person-years) in the decade prior to mandatory screening compared to the decade after (2.66 events per 100,000 person-years). The authors also called into question the findings from Italy (35) from which the ESC based their current guidelines (44), noting that the Italian study only looked at the 2-year period preceding the enforcement of ECG screening and compared this to mortality rates 25 years later. Instead, it may be that there were abnormally high mortality rates in Italy in 1980 and 1981 (mandatory screening was enforced in 1982) but if they had looked prior to those dates, they may have found great variability in the SCD rates, as was found in Israel (35,64).

As well, as with any screening tool, ECG does not detect all conditions that predispose an athlete to SCD. In particular, congenital coronary anomalies and premature atherosclerotic CAD cannot be identified by ECG alone. These cause up to 20% of SCD in young athletes in the United States (26). There are also a small percentage of people with HCM who have normal ECG; however, it is believed that these may represent a milder phenotype and may have a lower risk for cardiac-related sudden death (65).

Electrocardiogram Analysis

The evaluation of studies looking at false-positive and false-negative rates for ECG screening may be strongly affected by what is defined as normal and abnormal in an individual study. There are physiologic changes in structure and function that are considered benign in athletes but are atypical in a sedentary individual. These ECG changes that were once thought of as abnormal are now understood to be training-related changes. To clarify physiologic ECG changes in athletes from pathologic ones, the ESC recently published a statement with recommendations on ECG interpretations (66). These are summarized in Table 6.1. The main change from previous guidelines is the elimination of isolated QRS voltage criteria

TABLE 6.1 Classification of Abnormalities of the Athlete's ECG

Common and Training-Related ECG Changes	Uncommon and Training-Unrelated ECG Changes
Sinus bradycardia	T-wave inversion
First-degree AV block	ST-segment depression
Incomplete RBBB	Pathologic Q waves
Early repolarization	Left atrial enlargement
Isolated QRS voltage criteria for LVH	Left-axis deviation/left anterior hemiblock
	Right-axis deviation/left posterior hemiblock
	Right ventricular hypertrophy
	Ventricular preexcitation
	Complete LBBB or RBBB
	Long- or short-QT interval
	Brugada-like early repolarization

Common or training changes generally require no additional investigation. Uncommon changes should be further evaluated prior to sports participation.

Modified from Corrado D, Pelliccia A, Heidbuchel H, et al. Recommendations for interpretation of the 12-lead electrocardiogram in the athlete. *Eur Heart J* 2010;31(2):243–259.

for left ventricular hypertrophy (LVH) as abnormal. Several studies have demonstrated a high incidence (up to 80%) of ECGs from trained athletes that meet ECG LVH criteria (S wave in V1 + R wave in V5 >35 mm) (66).

Further, since most normative data for ECGs are based on Caucasian males, they may not extrapolate well to other populations. For instance, female adolescent athletes often have T-wave inversions in the right precordial leads, which may be mistaken for ARVC (67). Research has also shown that ethnicity impacts physiologic responses to exercise and, as such, may manifest with ECG patterns that are classified as abnormal. This is especially true of athletes of African and Afro-Caribbean descent. In a study by Magalski et al. (68) evaluating ECG patterns in 1,959 elite male football players in the United States, the authors found marked repolarization abnormalities, often limited to the right precordial leads (V₁–V₄), in 30% of African American athletes compared with 13% of Caucasian athletes. Another study from the United Kingdom suggested that certain electrocardiographic abnormalities found in black athletes may be variants of normal and not evidence of pathology. This study demonstrated that black athletes with ECG abnormalities limited to the right precordial leads did not have evidence of cardiomyopathy by echocardiography and, when followed long-term, these athletes had no increased cardiovascular morbidity or mortality (69).

Economic Consequence of Preparticipation Screening

When examining the cost-benefit ratio of preparticipation screening, one has to examine the cost of the ECG added to the cost of history and physical examination alone. There is high variability in reports of cost-effectiveness estimates based on different statistics used for rates of SCD, false-positive rates of ECG, and costs of ECG and additional screening (70). For example, since there are >10 million athletes in the United States, if an ECG costs \$50, it would cost \$500 million for electrocardiographic screening of all athletes. Based on the Italian

experience, we would estimate that 890,000 ECGs would be positive in the United States. This will result in ordering an echocardiogram at an approximate cost of \$1,500 per test. Thus, the total cost of an Italian/European-based screening program in the United States would be \$1.84 billion. This is coupled with the above data and is probably underestimating EKG and echo costs.

Fuller et al. (71) assessed the cost-effectiveness of using history and physical examination alone with the addition of a 12-lead ECG and found that adding an ECG was more cost-effective, costing \$44,000 per life-year saved if ECG screening was used on high school athletes in the United States compared with \$84,000 per life-year saved by history and examination alone. Recently, Wheeler et al. (72) evaluated the cost-effectiveness of preparticipation screening of U.S. athletes from ages 14 to 22 using cardiac-focused history and physical examination alone or with the addition of ECG. The authors found that the addition of 12-lead ECG saves 2.1 life-years per 1,000 athletes screened (\$89 per athlete) with a cost-effectiveness ratio of \$42,900 per life-year saved compared with history and physical examination alone.

Start-up costs of a preparticipation screening program in countries such as the United States, where there is not an established program in place, would be significant. There are not only costs in developing the necessary infrastructure for both the evaluation as well as the treatment of athletes but also the costs for physicians who would need to undergo more formalized training. There are also the costs and resources needed for those who have ECG abnormalities, since they almost always necessitate further evaluation, including visits with a cardiovascular specialist and noninvasive imaging, such as echocardiography. In those for whom the ECG is a false positive, the costs of additional testing are not only financial, but physical and psychological too. The athlete may experience anxiety awaiting further evaluation, will likely be restricted from exercise, and may be disqualified from the sport. This highlights the need for a program in which quick evaluation and results are provided to those who have abnormalities found at the initial screening process (37,73).

SPECIFIC CONGENITAL CARDIAC LESIONS

Shunt Lesion

Atrial Septal Defect, Ventricular Septal Defect, Atrioventricular Septal Defect and Patent Ductus Arteriosus

When exercise capacity is measured by formal exercise testing in patients with either small or repaired shunt lesions, many patients are found to have a low aerobic capacity (74,75). While residual cardiac disease or, more rarely, a persistent degree of pulmonary hypertension (PHT) with exercise may be the cause of this finding in a few cases (75), the cause in the majority of patients with these shunt lesions is a sedentary lifestyle with physical inactivity. Regular exercise participation, exercise training, and in many cases competitive sports participation may be beneficial for the majority of these patients.

Atrial Septal Defect

In patients with atrial septal defect (ASD), blood flows left to right across the atrial defect during diastole as a consequence of the greater right ventricular compliance. The total amount of blood across the shunt is negligible in small defects, and patients should have a normal exercise capacity. However, in larger defects the greater shunt size leads to right ventricular volume overload that could potentially cause PHT during exercise (75). In addition, this shunt flow may limit preload to the left ventricle at higher heart rates. If this occurs, this may lead to a mildly reduced exercise capacity. After ASD closure, nearly all patients resume full exercise capacity. In the current surgical and interventional era, repair outside of early childhood is rare. Residual PHT or atrial arrhythmias are very rare during childhood or at any age following early childhood repair. The guidelines from the 36th Bethesda Conference do not limit competitive activity in children who have their defects closed. The only patients in whom exercise should be restricted are those with a large ASD and mild pulmonary artery hypertension. Low-intensity competitive sports (IA) are recommended until the defect is closed (76). In Europe the guidelines from the task force of the ESC on sports for children with CHD and a left-to-right shunt (ASD) are for no limitations on physical exercise or sports activities (77). This also holds true for leisure sports and other physical activities.

After interventional device closure of the ASD, the patient may resume light sport activities approximately 10 to 14 days after intervention (i.e., when the puncture site at the groin has healed completely). To minimize risk of dislodgement, contact sports should be avoided for 6 months at which time the device should be completely covered by the endocardium. After surgical patch closure, there are no restrictions after the thoracotomy has healed.

Ventricular Septal Defect

In those patients with highly restrictive ventricular septal defects (VSD) with a pulmonary-to-systemic flow ratio (Qp/Qs) of $<1.5/1$, there will only be a small shunt from the left to right ventricle (RV). During exercise, the shunt will remain relatively small. In those with moderate-size defects (Qp/Qs 1.5–2), there is usually low pulmonary artery pressure and resistance and only mild left ventricular volume overload. In these patients, dynamic exercise is usually well tolerated. Because isometric exercise increases systemic afterload much more than pulmonary afterload, this form of exercise can result in an increase in both pulmonary flow and Qp/Qs , making isometric exercise somewhat less well tolerated. Those patients with large VSD ($Qp/Qs > 2$) with normal pulmonary pressures

and resistances have similar exercise hemodynamics compared to those with moderate-size defects. However, if there is PHT, neither dynamic nor isometric exercise is well tolerated. In the presence of significantly elevated PVR, the pulmonary vascular bed is unable to handle the increased blood flow associated with the exercise and right-to-left shunting may occur.

In two studies of children during submaximal exercise testing, reduced values for ventilatory anaerobic threshold were found in about half of 43 patients with native VSD (mean $86 \pm 12\%$ of normal) and with surgically closed VSD (mean $86 \pm 12\%$ of normal) (74,75). The only variable that correlated with a lower level of exercise performance was greater physical inactivity during daily life. Children with a VSD (repaired or unrepaired) should be encouraged to be physically active and to adopt a healthy lifestyle. If low levels of exercise performance are found, increasing physical activity should be encouraged. Previous studies in small groups of children with congenital heart defects, including those with VSD, have shown improvement in maximal work rate on the bicycle ergometer, without a change in maximal VO_2 after a 6-week home-based conditioning program (78).

Atrioventricular Septal Defects

Patients with an atrioventricular septal defect (AVSD) who do not have Down syndrome should follow the same recommendations as for VSD. The only exception is those individuals who have significant mitral regurgitation. Those with moderate to severe mitral regurgitation should be restricted from exercise if they have either severe volume overload of the left atrium and/or left ventricle or evidence of PHT. For those patients with Down syndrome, discussion with the primary physician and cardiologist should occur before undertaking any exercise program. While physical activity is important and encouraged in this population, they may need to be restricted from contact sports and other activities that may jar the neck due to the high rate of atlantoaxial instability in people with Down syndrome (79).

Patent Ductus Arteriosus

For patients with a patent ductus arteriosus (PDA), the hemodynamics are similar to those found in patients with VSD. When in isolation, PDA closure is nearly always performed percutaneously. The same recommendations for activity apply as after percutaneous ASD closure.

Evaluation Prior to Exercise and Sports Participation

Most patients with well-repaired or hemodynamically insignificant residual shunt defects need little evaluation beyond routine outpatient care prior to participating in either recreational or competitive athletics. This will generally include a physical examination, ECG, chest x-ray, and echocardiogram. In cases where there is additional concern of significant residual abnormalities or pulmonary disease, additional testing including exercise testing may be needed (76).

Leisure Activities and Activities of Daily Living

In patients with well repaired or hemodynamically insignificant ASD, VSD, PDA, and AVSD, no limitation exists for leisure activities or activities of daily living. These children can and should participate normally in physical exercise without restrictions. It is recommended that they perform 60 minutes of moderate to vigorous physical activity on 5 days per week or more (20) (see Table 6.2).

Competitive Sports

According to the Bethesda guidelines, since most children have ASDs closed before they are active in competitive sports,

exercise usually is not restricted. The only patients in whom exercise should be restricted are those with a large ASD (unrepaired) and mild pulmonary artery hypertension. Low-intensity competitive sports (IA) are recommended until the defect is closed (see Fig. 6.1). For those athletes with surgical or device closure of an ASD, if there is no evidence of PHT or ventricular or atrial ectopy, they can participate in all sports 3 to 6 months after the operation or device closure (76). For those with VSDs, athletes with small to moderate defects and normal pulmonary artery pressure can participate in all sports while those with large defects and normal pulmonary artery pressure can participate after VSD closure. Those with large unrepaired defects and elevated pulmonary vascular resistance cannot participate in competitive sports (76). For those who want to participate in competitive athletics after surgical or device closure of a VSD, if there is no evidence of PHT or ventricular or atrial ectopy, the patient can participate in all sports 3 to 6 months after successful intervention (76). Limitations for competitive sports are only in patients with pulmonary arterial hypertension (PAH) (77). Information on exercise recommendations for the patients with PHT can be found in the section on PHT later in this chapter.

Left-Sided Obstructive Lesions

Aortic Stenosis

Congenital aortic stenosis occurs in three major subtypes: subvalvar, valvar, and supravalvar. Subvalvar disease is a result of a subaortic muscular ridge, a fibromuscular ridge and/or tunnel, or a discrete subaortic membrane. Subaortic obstruction is also associated with a distorted aortic valve leaflet resulting in regurgitation. Congenitally stenotic aortic valves can be isolated, as is seen in the unicommissural or bicommissural lesions, or they can be found in association with posterior malalignment type VSD, abnormalities of the mitral valve, hypoplasia of the aortic arch, and aortic coarctation. Supravalvar aortic stenosis at the sinotubular junction is typically seen in patients with Williams syndrome, in familial supraaortic stenosis and rarely with familial dyslipidemias (80, 81), or as spontaneous mutations in otherwise normal individuals. Except in severe cases or in the presence of other significant defects, exercise performance is usually normal or near normal.

Evaluation Prior to Exercise and Sports Participation

It is important to distinguish symptomatic from asymptomatic patients who have aortic stenosis. A previous history of exercise-induced syncope or lightheadedness, dyspnea with exercise without an ostensible pulmonary etiology, or angina may indicate that these patients are at higher risk of SCD compared

to asymptomatic patients. These patients therefore should be evaluated for possible surgery or catheter-based interventions. Guidelines grading the degree of stenosis have been previously reported and have been used to make recommendations regarding sports participation in competitive athletes. However, these guidelines are admittedly conservative and based upon scant literature (76). Most of the previously reported patients with aortic stenosis who died suddenly had a high incidence of ECG abnormalities. LVH and/or strain should be assessed when making recommendations for competitive sports. Graded exercise testing may be helpful in unmasking important findings, such as blunted blood pressure response or ventricular ectopy, in asymptomatic patients.

Leisure Activities and Activities of Daily Living

As stated above, most patients with aortic stenosis are asymptomatic and have normal exercise tolerance. Patients with mild disease need no restrictions and should follow the recommendations in Table 6.2. Patients with moderate stenosis should follow the recommendations for bicuspid aortic valve syndrome (see Table 6.3). It is unknown if regular physical training slows the progression of stenosis or insufficiency in this disorder. It is believed that repetitive, maximally strenuous isometric exercise may hasten valve deterioration; therefore, these activities should be minimized or avoided completely. Physical training, however, is helpful in hastening recovery in patients with CHD who have had surgical intervention (82–84).

Competitive Sports

Patients with valvar aortic stenosis are at risk for SCD during exercise (26,85). However, the true risk is unknown. In adults, syncope, dizziness, angina pectoris, or dyspnea with exercise are associated with SCD. Recent data suggest that the risk of SCD during exercise in patients who had balloon valvuloplasty as infants may not be as high as previously believed (86). Until more data are available, the guidelines from the 36th Bethesda Conference are probably reasonable. Athletes with mild aortic stenosis, a normal resting ECG, and no history of exercise-related symptoms can participate in all forms of competitive sports. Patients with mild stenosis should be reevaluated periodically to continue with competitive sports. Athletes with moderate aortic stenosis who have mild or no LVH, normal response to treadmill exercise testing, and no exercise-induced symptoms can participate in low static/low-to-moderate dynamic and moderate static/low-to-moderate dynamic exercise (classes IA, IB, and IIA) (see Fig. 6.1). Individualized exercise prescriptions in borderline cases are reasonable in light of the finding of the lower risk of sudden death than was previously believed (86).

TABLE 6.2

Recommendations Following the F.I.T.T. Principle for Recreational Activities and Exercise Training in Children and Adolescents with ASD/VSD/AVSD/PDA and No Hemodynamically Significant Residual Disease

F.I.T.T.	Cardiovascular (dynamic) Training	Muscle (static) Training
Frequency	Moderate: daily Vigorous: 3–5×/wk	3–5×/wk
Intensity	Moderate: 55%–60% of max $\dot{V}O_2$ to Heavy: below 80% of max $\dot{V}O_2$	Moderate to High: 20%–50% MVC to >70% MVC
Time	Most of daily 60 min activity	As part of daily 60 min activity
Type	Predominantly dynamic activity: e.g., running, jumping, cycling, swimming, inline skating, skateboarding, soccer	Predominantly static activity: e.g., gymnastics, climbing, push-ups, martial arts, ball sports practice

$\dot{V}O_2$, minute oxygen consumption; MVC, maximum voluntary contraction.

TABLE 6.3

Recommendations Following the F.I.T.T. Principle for Recreational Activities and Exercise Training in Children and Adolescents with Bicuspid Aortic Valve Syndrome^a

F.I.T.T.	Cardiovascular (dynamic) Training	Muscle (static) Training
Frequency	3–4×/wk	1–2×/wk
Intensity	Constant load training at low to moderate intensity: 40%–60% of max $\dot{V}O_2$	Low intensity: (i.e., 1–5 lb Dumbbells), 10–15 repetitions for separate small muscle group
Time	60 min per session	Include up to 30 min strength training in total time.
Type	Low static sports, like cycling, walking, swimming	Dumbbell exercises, light gymnastics.

$\dot{V}O_2$, minute oxygen consumption.

^aPatients with no aortic root dilation and no significant stenosis or regurgitation may follow recommendations in Table 6.2.

Subvalvar and supra-avalvar aortic stenosis probably warrant similar exercise recommendations as valvar aortic stenosis, even in light of slightly different pathophysiologies.

Bicuspid Aortic Valves

Bicuspid or bicommissural aortic valves are the most common type of congenital heart malformation, estimated to occur in 0.5% of the population. Males are affected three times more often than females (87,88). Many providers investigate for Turner syndrome when a female is found to have a bicuspid aortic valve. In females with bicuspid aortic valve in association with coarctation, Turner syndrome or Turner mosaicism should be strongly considered. The typical bicuspid aortic valve has two recognizable lines of cusp apposition. Fusion of the right and left or right and noncoronary cusps results in valves that are prone to either regurgitation or stenosis or both. Abnormalities of the aortic root, sinotubular junction, and ascending aorta occur as part of this lesion (89–91). Dilation of the root and ascending aorta is common, even in patients who do not have stenosis or regurgitation. The risk of spontaneous rupture may occur in these patients but with much less frequency compared to Marfan syndrome patients. There is a tendency to dilate the aortic root in patients with fusion of the right and left coronary cusps, while dilation of the ascending aorta appears to be more common in patients with fusion of the right and noncoronary cusps (92,93).

Evaluation Prior to Exercise and Sports Participation

Bicuspid aortic valves should be considered when there is a family history of aortic valve problems in first-degree relatives (siblings or parents) given the reported vertical transmission rate as high as 33% with this defect. The physical finding of an aortic ejection click is frequently found with this anomaly, and a stenotic or regurgitant murmur may be present. Four extremity blood pressure assessments will help rule out coexisting aortic coarctation. ECG screening is uniformly performed but is typically not helpful when no significant murmurs are present on the physical examination. ECG is essential in determining the diagnosis and assessing the hemodynamic significance of the lesion or lesions. Exercise stress testing is not usually helpful, unless important stenosis and/or regurgitation is found echocardiographically or if coarctation of the aorta is also identified. Magnetic resonance imaging (MRI) may be helpful in assessing the caliber of the ascending aorta in patients who have difficult ECG windows. Cardiac catheterization may rarely be needed to confirm the gradient in patients who appear to have moderate-to-severe stenosis and may be helpful for risk stratification.

Leisure Activities and Activities of Daily Living

These patients should follow the guidelines listed above for aortic stenosis. Minimizing the exposure to significant static activities should be emphasized in those patients with evidence of aortic root dilation. These recommendations are summarized in Table 6.3.

Competitive sport

Patients with isolated bicuspid aortic valve without stenosis, regurgitation, or aortic dilation may participate in all competitive sports. Although there is information to suggest that regular athletic training may increase aortic dimensions, the actual risk associated with this progression is unknown (94). There is evidence that endurance training may improve the elastic properties of the aorta (95–99). Close follow-up is warranted, and annual ECG may be helpful (100) but should be individualized to the patient. Intense, repetitive isometric activities may enhance aortic stiffness (101) and dilation (102); however, in the absence of aortic root dilation, isometric activities are currently acceptable (103).

Exercise restrictions are implemented for regurgitant and/or stenotic aortic valves, and the degree of restriction is commensurate with the degree of the hemodynamic abnormality (103). Mild aortic dilation does not typically indicate exercise restrictions; however, frequent (annual) assessment is required in athletes, with attention to both the absolute dimension and rate of change. Current recommendations are summarized below. In younger preadolescent ages, the aortic root size should be indexed to the appropriate body mass Z-score.

1. Patients with isolated bicuspid aortic valve without important stenosis or regurgitation and no more than mild aortic dilation (<40 mm) may participate in all competitive sports.
2. Patients with moderate (<45 mm) aortic dilation that is stable (not rapidly progressive) may participate in low static/low-to-moderate dynamic competitive sports without risk of bodily collision.
3. Patients with progressive (>5 mm per year) or severe aortic dilation (>45 mm) are permitted to engage in low static/low dynamic exercise only.

Coarctation of the Aorta

Aortic coarctation is narrowing of the aortic isthmus, defined as the segment of the aorta between the origin of the subclavian artery and ductal ampulla/ligament. It is commonly associated with abnormalities of the aortic valve, VSD, mitral valve abnormalities, hypoplasia of the transverse aortic arch, and hypoplastic left heart syndrome. Histologic abnormalities

involving the elastic media at the site of the coarctation are integral to this lesion. Older unoperated patients are also at risk for the development of and rupture of intracranial aneurysms. This risk exists even in operated patients. The cardiovascular risk of CAD, stroke, heart failure, aortic and cerebral aneurysmal rupture, and SCD occur even after successful early repair (104). Exercise capacity is reduced in these patients despite the adequacy of the repair (105,106). Chronically elevated systolic blood pressure may play a role in cardiovascular morbidity and mortality. Endothelial dysfunction, reduced vessel elasticity, and enhanced baroreceptors may all play a role in the development of chronic systolic hypertension and the commonly found systolic hypertensive rise to graded dynamic or isometric exercise (107–109).

Evaluation Prior to Exercise and Sports Participation

Medical and surgical history, including the presence and/or repair of associated lesions, four extremity blood pressures, and a resting ECG are essential in the initial evaluation of patients with coarctation of the aorta. Previous information regarding cardiac catheterizations is also important, particularly in patients who have had balloon dilation of native coarctation or dilation of recurrent/residual coarctation. The presence of an upper-to-lower extremity blood pressure gradient should alert the physician to the presence of a possible residual coarctation.

Laboratory studies include the baseline resting ECG to assess for the presence of LVH. Echocardiography is very useful in the detection of residual gradients, associated lesions, and the site of the residual obstruction, if present, as well as LVH. MRI with three-dimensional reconstruction offers exquisite detail of aortic anatomy and may be useful in determining the site of residual obstruction or aneurysm. Maximal exercise testing can be useful to assess the blood pressure response to exercise in these patients. This response may be abnormal even in the absence of a residual coarctation. This may be related to residual abnormal vascular reactivity that may be seen in these patients as stated above.

Leisure Activities and Activities of Daily Living

There are significant numbers of studies examining exercise performance in patients with repaired coarctation of the aorta but longitudinal data regarding the risk of intense exercise participation and training are sparse. Those patients with good repairs (e.g., resting gradient of <20 mm Hg, no juxtaductal aneurysm), normal resting and exercise blood pressures, and no other associated cardiac abnormalities should engage in regular moderate to vigorous recreational activities as outlined in Table 6.2. Those patients with hypertension in the absence of residual coarctation should follow the recommendations listed later in this chapter for systemic hypertension. Patients with a bicuspid aortic valve should follow the recommendations for bicuspid valves in Table 6.3.

Competitive Sports

Patients with isolated coarctation of mild degree (<20 mm Hg systolic blood pressure gradient) may participate in all sports; however, activities that have a maximally strenuous isometric component should probably be discouraged. Patients with residual obstruction should be referred for either catheter-based or surgical intervention prior to participating in competitive sports (76). Resting or exercise-induced hypertension in the absence of a residual gradient should be treated as discussed in the section on systemic hypertension. As with recreational activities, competitive sports in patients with repaired coarctation and bicuspid aortic valve should defer to the section on bicuspid aortic valve.

Right-Sided Obstructive Lesions

Pulmonary Stenosis

Valvar pulmonary stenosis (PS) is the most common type of right ventricular outflow obstruction and is caused by fused leaflets in most cases. The degree of obstruction is variable, but is typically mild and may regress spontaneously. More advanced obstruction results in right ventricular hypertrophy and/or strain, and if left untreated, can result in exercise intolerance (110), and/or atrial arrhythmias secondary to right atrial dilation. Most patients with advanced obstruction benefit from intervention, typically balloon valvuloplasty. Freedom from reintervention and exercise capacity have been reported to be quite favorable; however, the long-term impact of chronic pulmonary regurgitation as a result of the intervention remains to be seen (111,112). Mild PS (peak gradient <30 mm Hg) does not appear to significantly impact exercise performance. However, moderate (30 to 50 mm Hg peak gradient) or severe (>50 mm Hg) stenosis impairs performance, but typically improves after intervention.

Evaluation Prior to Exercise and Sports Participation

Prior to participation in routine physical activity, patients with PS should have a complete cardiovascular physical examination. A resting ECG should be obtained. Further studies will depend on the severity of the stenosis and the extent of any associated additional cardiac abnormalities. An echocardiogram, Holter monitor, and exercise testing should be considered in any patient with more than mild PS. Additional imaging studies such as cardiac MRI or computed tomography (CT) scan may be needed in select patients with significant right ventricular dilation or dysfunction.

Leisure Activities and Activities of Daily Living

Patients with mild PS not associated with a pressure overloaded RV, no ECG abnormalities, and normal exercise tolerance are encouraged to pursue normal activities (see Table 6.2) (76,113,114). Patients with treated PS and no significant hemodynamic abnormalities (mild stenosis, no more than moderate regurgitation) and a normal ECG should also be encouraged to participate in recreational activities without restrictions. Similar recommendations apply for patients with moderate stenosis and no more than moderate regurgitation.

For patients with residual regurgitation associated with a dilated RV with normal RV systolic wall motion (see Table 6.4). If RV dysfunction is present, recreational activities and daily living activities may be limited. These patients may benefit from a formal exercise prescription to help optimize both their dynamic and static exercise performance (see Table 6.5). Patients with severe stenosis should be restricted from exercise until they can undergo repair.

Competitive Sports

Patients with mild PS, normal RV size and function and no more than mild regurgitation, normal ECG, and no RV hypertrophy, may participate in all sports (76,115). Patients with moderate stenosis, no more than mild regurgitation, normal RV size and function, normal ECG, and no more than mild RV hypertrophy can participate in no more than moderate dynamic and mild isometric sports (see Fig. 6.1) (76,115). Patients with no or mild stenosis but with significant regurgitation associated with RV dilation but normal RV function and are asymptomatic, can participate in low-intensity aerobic activities (see Fig. 6.1). Patients with severe stenosis should not engage in competitive sports but they can resume sports 3 to 6 months after successful intervention. Types of activities depend upon residual hemodynamic findings (see above) (76,115).

TABLE 6.4 Recommendations Following the F.I.T.T. Principle for Recreational Activities and Exercise Training in Children and Adolescents with PS and ToF and Moderate Residual Lesions and No Right Ventricular Dysfunction

F.I.T.T.	Cardiovascular (dynamic) Training	Muscle (static) Training
Frequency	3–5×/wk to daily	3–5×/wk
Intensity	Moderate: 40%–60% of max VO_2	Low to moderate: 20%–50% MVC
Time	Most of daily 60 min activity	As part of daily 60 min activity
Type	Moderate dynamic activities including swimming, table tennis, walking	Static activities including gymnastics, ball sports, light weights

VO_2 , minute oxygen consumption; MVC, maximum voluntary contraction.

Tetralogy of Fallot

Exercise performance in Tetralogy of Fallot (TOF) has probably been studied more than in any other congenital cardiac abnormality. Valvotomy and outflow tract patches typically result in pulmonary regurgitation and dilation of the RV. Significant ventricular dilation can lead to arrhythmias as can scarring associated with ventriculotomies. Residual stenosis, regurgitation, and branch pulmonary artery stenosis have all been independently associated with diminished exercise performance, and inefficient ventilation during exercise. The latter is manifested as high ventilatory equivalents for carbon dioxide (minute ventilation is high when compared to carbon dioxide excretion) as well as a steep rise in the slope of minute ventilation relative to carbon dioxide production (116–119). Exercise capacity varies widely in this population. It may range from severely depressed to, in some cases, well above normal. This heterogeneity in exercise performance reflects both the heterogeneity of the defect itself as well as the broad spectrum of residual disease seen following operative repair. Those patients with significant pulmonary regurgitation accompanied by biventricular systolic dysfunction appear to have the lowest exercise capacity (117). These are often young adults with long-standing residual right-sided abnormalities. Patients with restrictive right ventricular mechanics may not develop significant right ventricular dilation despite severe pulmonary regurgitation and often appear to have more preserved exercise capacity at long-term follow-up (120,121). QRS prolongation is associated with

dilated RVs, and the absolute measurement (>180 ms) as well as the rate of change of the QRS duration may be important prognosticators for the risk of SCD during exercise. Other factors associated with ventricular arrhythmias and possibly with SCD include older age at repair, residual right ventricular outflow tract obstruction with increased right ventricular systolic pressure, RV dilation and dysfunction, and left ventricular systolic dysfunction (122–125). Premature atrial and ventricular ectopy is commonly observed on exercise testing and can be seen in as many as 50% of patients. However, fast atrial or ventricular couplets or runs of arrhythmias are not common during exercise testing and are likely a cause for concern.

Recent studies in young adults have shown a significant predictive value of exercise testing for identifying patients at risk for either SCD or death from heart failure as well as the need for hospitalization for heart failure. Several studies assessing the role of exercise training in a controlled environment have also demonstrated improvement in exercise performance in this population despite the presence of important residual lesions (pulmonary regurgitation, RV dysfunction). Of note is that in one such study, patients with documented ventricular arrhythmias were excluded from participation (126).

Evaluation Prior to Exercise and Sports Participation

Evaluation prior to participation in regular physical activity should be similar to that for PS with residual cardiac abnormalities. All patients should have regular Holter monitoring

TABLE 6.5 Recommendations Following the F.I.T.T. Principle for Recreational Activities and Exercise Training in Children and Adolescents with PS and ToF and Residual Lesions with Right Ventricular Dysfunction^a

F.I.T.T.	Cardiovascular (dynamic) Training	Muscle (static) Training
Frequency	3–5×/wk to daily	3–5×/wk
Intensity	Low to moderate: 30%–60% of max VO_2	Low to moderate: 20%–50% MVC
Time	Most of daily 60 min activity	As part of daily 60 min activity
Type	Low to moderate dynamic activities including walking, swimming	static activities including light gymnastics, ball sports, light weights

VO_2 , minute oxygen consumption; MVC, maximum voluntary contraction.

^aConsider formal exercise prescription in patients with significant cardiac dysfunction or deconditioning.

and exercise testing to evaluate arrhythmias and assess cardiopulmonary capacity during exercise. Exercise testing combined with imaging studies, such as MRI, may be helpful in identifying patients who could benefit from pulmonary valve replacement. This may be especially useful in the late adolescent and young adult age group.

Leisure Activities and Activities of Daily Living

Because of the heterogeneity of this population, recommendations for activities and sports participation will vary widely depending on the state of the individual patient. Asymptomatic patients with normal or only mild RV dilation, normal right ventricular pressure, and systolic function who have no documented arrhythmias at rest and during exercise should be encouraged to pursue regular physical activities without restrictions (see Table 6.2).

Asymptomatic patients with significant pulmonary regurgitation who have at least moderate right ventricular dilation, but with preserved right ventricular function and no arrhythmias at rest or during exercise should follow recommendations as delineated in Table 6.4.

Asymptomatic patients with significant regurgitation, significant right ventricular dilation, and abnormal function may engage in mild dynamic exercise assuming no arrhythmias at rest or during exercise. These patients as well as the symptomatic patients described in the following paragraph may benefit from a formal exercise prescription to better assess their individual limitations and to assure that they are performing activities that are safe and appropriate for their individual capacities. Depending on the patient, this may be based on recommendations in Tables 6.4 or 6.5.

Symptomatic patients with residual right ventricular lesions and/or left ventricular dysfunction, patients with right ventricular to systemic systolic pressures ratios of two-thirds or more, patients with important residual intracardiac shunts, and patients with documented sustained atrial or ventricular arrhythmias that are refractory to treatment should engage in only low dynamic, low static activities (see Table 6.5).

Competitive Sports

Repaired patients with normal or near-normal RV pressure, with no more than mild RV volume overload, no important residual shunt, and no arrhythmias at rest or during exercise may engage in all competitive sports without restriction, except in Europe (76,115). The recent extraordinary performance of an American freestyle snow boarder is testament of the safety of the pursuit of athletic competition at very high level in repaired patients who do not have significant residual lesions. Patients with pulmonary regurgitation with dilated RVs, elevated RV pressures to one-half or more of the systemic systolic pressure, or with atrial or ventricular arrhythmias should only engage in low static, low dynamic sports (see Fig. 6.1) (76).

Ebstein Anomaly

There is scant literature regarding exercise performance and the risk associated with exercise in patients with Ebstein anomaly. Heterogeneity in this patient population is great and will vary with the severity of the valvular abnormalities as well as with the presence and degree of atrial right to left shunting. Oxygen consumption is reduced compared to normal. However, patients have improved exercise performance after tricuspid valvuloplasty and ASD closures (127). Patients repaired at a younger age who have lower cardiothoracic ratios on chest x-ray at the time of intervention appear to have the best outcomes. Preoperative patients frequently have cyanosis at rest that worsens with exercise. Even after surgical intervention,

most patients have fairly limited exercise capacity with an average maximal VO_2 of 50% of predicted. Chronotropic impairment may be present. Reduced right ventricular and left ventricular stroke volumes may limit cardiac output and therefore exercise performance, even in adult patients who are fully saturated (128). Similar to patients with TOF and single ventricles, ventilatory inefficiency during exercise can be significant as a result of pulmonary abnormalities as well as right-to-left intra-arterial shunting if an ASD is present.

Evaluation Prior to Exercise and Sports Participation

Evaluation prior to participation in regular physical activity should be similar to that outlined for patients with TOF. Exercise testing and Holter monitoring are useful to assess exercise-induced arrhythmias and evidence of preexcitation. Exercise testing is also useful to evaluate the presence and degree of desaturation with exercise.

Leisure Activities and Activities of Daily Living

Asymptomatic, acyanotic patients with no more than mild tricuspid regurgitation, normal left ventricular systolic function, and no resting or exercise-induced arrhythmias may engage in all activities (Table 6.2). Asymptomatic patients with moderate tricuspid regurgitation and normal arterial saturation with supraventricular arrhythmias that are controlled may participate in low-level dynamic and no more than moderately isometric physical activities (see Table 6.5). Symptomatic patients at rest or during exercise, those with important right atrial or right ventricular dilation, severe regurgitation, left ventricular dysfunction, or chronic atrial or ventricular arrhythmias, should not engage in physical exercise.

Competitive Sports

Asymptomatic, acyanotic patients with no more than mild tricuspid regurgitation, normal left ventricular systolic function, and no resting or exercise-induced arrhythmias may engage in all competitive sports (76). Asymptomatic patients with no more than moderate tricuspid regurgitation, normal arterial saturation, and no resting or exercise-induced arrhythmias may participate in low dynamic and low static competitive sports (76) (see Fig. 6.1).

Patients with severe Ebstein anomaly characterized as severe regurgitation and evidence of right ventricular dysfunction (desaturation, exercise-induced arrhythmias, or symptoms during exercise or rest) should not engage in competitive sports. Patients who have had surgical intervention may participate in selected competitive sports 3 months after surgery if they are asymptomatic, have no or mild tricuspid valve regurgitation, and have no resting or exercise-induced arrhythmias.

D-Transposition of the Great Arteries

Prior to approximately 25 years ago, D-transposition of the great arteries (D-TGA) was repaired using the atrial switch operation, either the Mustard or Senning. Therefore, almost all patients with this type of procedure are in at least their third or fourth decade of life. Exercise performance in this population is usually moderately compromised with maximal VO_2 in the range of 60% to 70% of predicted. Many patients may be more severely limited even in performing activities of daily living to varying degrees. The reasons for poor exercise performance are multiple and may include poor systemic right ventricular function, chronotropic impairment, tricuspid valve regurgitation, and ridged atrial baffles that limit augmentation of ventricular preload (129–133).

Because of the long-term problems with the atrial switch operations, the current approach has been to perform an

arterial switch operation whenever possible. Most patients after the arterial switch operation have near-normal exercise performance (on average, 87% of predicted maximal VO_2) (134–140). However, as this population has moved into adolescent and young adult ages, there is evidence to suggest that their exercise performance has somewhat declined (137–139). The reasons for this decline are unclear but may be related at least in part to lack of physical activity and rising rates of obesity (3,4). Symptomatic and asymptomatic occlusion of coronary vessels, myocardial perfusion imaging defects, wall-motion abnormalities on stress echocardiography and diminished coronary reserve have been noted in approximately 10% to 12% of patients following the arterial switch operation (134,136,137,140–142). These findings raise concerns regarding the risk of highly competitive sports in these patients as well as the potential risks of acquired atherosclerotic coronary disease and subsequent activity-related myocardial ischemia as this population ages. Additionally, dilation of the aortic root is seen with increasing frequency as this population ages. Despite these concerns, sudden death after this operation is uncommon. To date, the need for surgical intervention has been quite low, and indications for reoperation are not clear. The risk for aortic rupture or dissection during activity in this population is not known but given the presence of scar tissue surrounding the aortic root and the presence of a suture line, it is probably much less than with aortic root dilation from connective tissue diseases. The effects of aortic root dilation on the coronary arteries are also unknown (143–145).

Evaluation Prior to Exercise and Sports Participation

Patients with the atrial switch operation will be almost exclusively adults, and most will have some degree of significant cardiac dysfunction. A thorough evaluation such as what was outlined above for patients with TOF with significant residual defects is warranted. Routine exercise testing is useful to assess for the presence of arrhythmias and chronotropic response. In addition, this testing is useful in judging exercise capacity and potential limitations. This information will be useful in helping to counsel patients about jobs and daily living activities as well as recreational sports and the need for physical rehabilitation, when necessary.

Following the arterial switch operation, a complete history and physical examination are also needed. An echocardiogram to assess for function, aortic root dilation, and pulmonary artery stenosis should be included. An exercise test may help to unveil hidden residual hemodynamic abnormalities or arrhythmias as well as to evaluate presence of ECG changes suggestive of myocardial ischemia. Myocardial perfusion imaging during exercise stress testing, stress echocardiography, and MRI may also be considered if abnormalities are suspected, especially in cases where resting conduction abnormalities on the ECG limit the interpretation of ST segment changes. Some authorities believe that ECG, echocardiography, and stress testing should be repeated every 2 years. However, there are no reliable data to suggest that this approach to screening frequency is superior to individual provider judgment.

Leisure Activities and Activities of Daily Living

The rare patients with atrial switch physiology who are asymptomatic and without residual abnormalities (ventricular dysfunction and no resting or exercise-induced arrhythmias) are encouraged to engage in a variety of recreational sports without restrictions (115,146). Because most of these patients will have some degree of cardiac, pulmonary, and/or musculoskeletal abnormalities, following the guidelines in Tables 6.4 and 6.5 is generally appropriate. Individual exercise prescriptions

based on exercise testing may frequently be useful to help with assessing the feasibility and safety of occupational as well as recreational activities.

Asymptomatic patients following repair using the arterial switch operation with no and/or minor residual lesions (small VSD, mild neopulmonary or neo-aortic stenosis or insufficiency), extra systoles without fast couplets or arrhythmias, and no exercise-induced arrhythmias are encouraged to engage in recreational sports without restrictions (see Table 6.2). Asymptomatic patients with hemodynamically significant residual lesions (ventricular dysfunction, hypertrophy, or dilation; neopulmonary stenosis >30 mm Hg; moderate or more neo-aortic regurgitation or arrhythmias at rest or during exercise) should be evaluated on an individual basis by their cardiologist. These patients generally should be able to exercise to their own tolerance level, avoid intravascular volume depletion, and be allowed to rest when fatigued. Maximally strenuous isometric activities, even for brief time periods, should probably be avoided. This makes sense as well for those patients with significant aortic root dilation. They may benefit from following the guidelines for patients with a bicuspid aortic valve and root dilation (see Table 6.3). However, as stated above, the risks of physical activities in this group of patients are unknown.

Competitive Sports

Almost without exception, patients repaired by the atrial switch operation are beyond the age when they would be likely to engage in organized competitive athletics. For the very rare patient with exceptionally good function who desires to participate in a recreational sport at a high level, comprehensive individual evaluation by their cardiologist should be undertaken prior to participation.

Asymptomatic patients repaired by the arterial switch operation with only minor residual lesions who have no significant arrhythmias at rest or during exercise and no evidence of exercise-induced myocardial ischemia may participate in competitive sports without restrictions. Sports with a combined high dynamic and high isometric component are not contraindicated, but are discouraged (see Fig. 6.1) (7,115). Patients with either symptoms possibly attributable to residual lesions or those with hemodynamically significant residual lesions are advised not to participate in competitive sports. Their cardiologist may prescribe sports with low dynamic and low isometric components depending upon the residual lesions and the needs of the patient.

Congenitally Corrected Transposition of the Great Arteries

Congenitally corrected transposition of the great arteries (ccTGA) is a relatively rare defect. Although ccTGA can occasionally occur with no other associated abnormalities, more than 90% of patients will have some additional defect or dysfunction. These additional defects may include VSD, tricuspid valve abnormalities, and left ventricular outflow obstruction. It is often these additional defects that are responsible for the decreased exercise performance in ccTGA. Abnormalities of the conduction system resulting in heart block are also common and adversely affect exercise performance.

Until recently, most patients with ccTGA were palliated with operations that resulted in the RV remaining the systemic pumping chamber. Therefore, studies of exercise performance in ccTGA are essentially restricted to these types of palliation. There are no significant data on the exercise performance after the so-called “double switch” operation.

Most exercise data are from studies in young adult populations with ccTGA comparing them to patients with D-TGA with atrial switch physiology. On average, the two groups are similar with maximal VO_2 of approximately 60% of predicted

for age and sex (147,148). The reasons for decreased exercise tolerance are similar to D-TGA: poor systemic RV function, tricuspid insufficiency, and chronotropic impairment. Interestingly, patients with ccTGA appear to be able to increase their stroke volume with exercise to a greater degree than those with D-TGA. This is a consequence of the lack of an atrial baffle in ccTGA allowing for better maintenance of right ventricular preload with exercise (132).

Evaluation Prior to Exercise and Sports Participation

Patients with ccTGA should have, in addition to a physical exam, a resting echocardiogram to assess right ventricular and left ventricular function, tricuspid valve function, and the presence and degree of ventricular outflow obstruction. A Holter monitor is useful to assess presence of conduction abnormalities. A maximal graded exercise test is useful to measure physical working capacity, aerobic capacity, chronotropic response, and presence of arrhythmias.

Leisure Activities and Activities of Daily Living

In most cases, activity recommendations for patients with ccTGA are similar to those with D-TGA repaired with an atrial switch operation. Regular recreational activities of light to moderate aerobic intensities should be encouraged on a daily level. Static activity should be at a low level especially in the presence of significant tricuspid insufficiency. In certain cases where there are little or no other associated abnormalities, higher levels of activity may be encouraged. This decision should be based on preparticipation evaluations and exercise testing.

Competitive Sports

As with leisure activity, recommendations for competitive sports are similar to those with D-TGA repaired with the atrial switch operation. These recommendations are to restrict to low dynamic and low static activities. Also, as with leisure activities, exceptions may be indicated in the rare patient with no significant associated abnormalities and normal ventricular and atrioventricular valve function. Frequent assessment of such patients is needed to assure safe participation in more vigorous activities.

Single Ventricle Physiology

Although patients with Fontan physiology have improved exercise tolerance compared to unoperated patients with single ventricles, their aerobic performance remains, in most cases, well below that of their age-matched peers and is also lower than that of most patients with other types of congenital heart defects. Most Fontan patients have a maximal VO_2 which approximates 65% to 70% of predicted, and have chronotropic impairment, reduced stroke volume, and impaired ventilatory inefficiency (149,150). Diminished muscle bulk and function may also contribute to reduced exercise tolerance (151). Submaximal aerobic capacity appears to be somewhat better preserved in this population. This finding may reflect the limited ability of this physiology to maintain ventricular preload at higher heart rates (149). Energy loss through the Fontan circuitry due to turbulence may limit the ability to augment cardiac output with exercise (152). Heart block and the loss of sequential atrioventricular conduction and sinus node dysfunction may also affect performance. There are increasing data showing that aerobic capacity and exercise tolerance declines in this population as they progress through their second and third decade of life. A significant decline in aerobic performance has been associated with onset of symptomatic heart failure and cardiac death or need for heart transplantation (23).

Evaluation Prior to Exercise and Sports Participation

Prior to undertaking a regular physical activity or conditioning program, patients with stable Fontan physiology should have a thorough baseline evaluation. Baseline testing should include an ECG, echocardiography to rule out hemodynamic derangements that may negatively impact the Fontan circuit, and a Holter monitor to assess for occult arrhythmias. A graded exercise test is extremely useful to measure aerobic and physical working capacities. Systemic oxygen saturation should be assessed throughout the test. Evaluating pulmonary function at rest and exercise may be quite useful in unmasking associated pulmonary abnormalities that may impact on exercise performance.

Leisure Activities and Activities of Daily Living

Patients with stable Fontan physiology are typically able to engage in normal daily activities without impairment. Patients should be encouraged to perform moderate to vigorous activities daily. Although exercise performance is quite limited in this group of patients, the variation in performance is great. On formal exercise testing, up to 25% to 30% of patients with Fontan physiology will have aerobic capacities within the range of normal for healthy age-matched peers. Not surprisingly, these patients tend to cluster in the preadolescent age range. These patients can and often do keep up with their peers with all levels of recreational activity.

At the other extreme, a significant portion of patients with Fontan physiology have quite limited exercise performance. These patients are often adolescents and young adults. These patients may have difficulty even with routine activities of daily living. Exercise training in accordance with the FITT principle, Table 6.6, has been shown to improve exercise capacity in Fontan patients (151,153–157). Patients should be allowed to rest when fatigued, maintain adequate hydration, and avoid bodily collision if taking antithrombotic medication.

Competitive Sports

The issue of participation in competitive sports in this population is complex. For reasons stated above, most adolescents and young adults with Fontan physiology are unlikely to be able to successfully compete in sports with moderate or greater dynamic and static requirements (Fig. 6.1). Therefore, the recommendations of the Bethesda Conference restricting them from those activities are a reasonable default position (76). Because there are exceptional patients in this age range with normal exercise capacity, a case-by-case evaluation should be made for these patients who may wish to compete at higher levels of intensity. The risks should be carefully evaluated and discussed with the patient and family.

As previously mentioned, preadolescent patients with Fontan physiology may often have normal or near normal exercise capacity. Also, as discussed earlier in this chapter, the nature of competitive sports in this population is significantly different from that of adolescent and adult level sports. There are no compelling data to support restricting this population from participation on the basis of their physiology alone. Rather, restrictions should be based on the patient's ability and assessment of their risks as outlined above.

In all patients with Fontan physiology, certain concerns should be addressed. Patients should not participate in competitive sports in which a risk of bodily collision could result in significant injury for those patients on antithrombotic medication, who are pacemaker-dependent or have implantable cardioverters/defibrillators. Patients must be allowed to rest when fatigued and maintain adequate hydration to minimize spontaneous clot formation, particularly those patients with atrial fenestrations.

TABLE 6.6 Recommendations Following the F.I.T.T. Principle for Recreational Activities and Exercise Training in Children and Adolescents with Fontan Procedure^a

F.I.T.T.	Cardiovascular (dynamic) Training	Muscle (static) Training
Frequency	3–5×/wk to daily	3–5×/wk
Intensity	Low to Moderate: 30%–60% of max $\dot{V}O_2$	Low: 20%–30% MVC
Time	30 min	15–30 min
Type	Walking, swimming, stationary cycle	light weights

$\dot{V}O_2$, minute oxygen consumption; MVC, maximum voluntary contraction.

^aConsider formal exercise prescription in patients with significant cardiac dysfunction or deconditioning.

Pulmonary Hypertension and Eisenmenger Syndrome

The classification of PHT was recently updated at the 4th World Symposium on Pulmonary Hypertension in 2008. In the pediatric population, the vast majority of patients who will be evaluated by a cardiologist will be in the PAH group. This includes patients with idiopathic, heritable, and PHT from CHD. This latter group also contains those patients with Eisenmenger physiology (158).

Functional classification for PHT is divided into four classes by the World Health Organization (see Table 6.7) (159). Class 1 patients are asymptomatic at rest and exercise. Class 2 patients are symptomatic with leisure activities and some activities of daily living. Classes 3 and 4 are significantly symptomatic even with activities that are generally less than those required for daily living. Even those patients who are Class 1 and 2 may be at significant risk with physical activity. SCD is a common cause of death in this population and occurs frequently during some type of physical activity. Of note, patients with Eisenmenger syndrome often have a more severe functional classification and yet are at lower risk for SCD with activities. The presence of a large cardiac shunt permits systemic cardiac output and coronary perfusion to be maintained in the face of a sudden increase in pulmonary

resistance or a drop in systemic resistance. Patients with PAH and a structurally normal heart may be unable to maintain cardiac output and system blood pressure with exercise in the face of significantly elevated pulmonary vascular resistance (160).

Evaluation Prior to Exercise and Sports Participation

This population is at high risk for adverse events with exercise even if they are completely asymptomatic. Evaluation and risk stratification of patients with PHT is complex and requires extensive testing that often includes noninvasive imaging studies and, frequently, cardiac catheterization to assess pulmonary vascular reactivity. This evaluation should be undertaken by a practitioner who is experienced in the diagnosis and treatment of PHT (160).

Evaluation of exercise performance is very useful in both initial risk stratification and subsequent monitoring of disease progression and therapeutic interventions. In mild cases, formal metabolic exercise testing can be used to monitor patients. In more severe cases, a 6-minute walk test has been shown to be useful both to monitor disease progression and to assess the efficacy of intervention. This type of testing may be needed as frequently as every 3 to 6 months (160).

TABLE 6.7 Functional Classification for Pulmonary Hypertension According to the World Health Organization

Class	Description
Class I	Patients with PHT but without resulting limitation of physical activity. Ordinary physical activity does not cause undue dyspnea or fatigue, chest pain, or near syncope.
Class II	Patients with PHT resulting in slight limitation of physical activity. They are asymptomatic at rest. Ordinary daily physical activities result in excessive dyspnea or fatigue.
Class III	Patients with PHT resulting in marked limitation of physical activity. They are asymptomatic at rest. Less than ordinary daily activities result in excessive dyspnea, fatigue, chest pain, or near syncope.
Class IV	Patients with PHT with inability to carry out any physical activity without symptoms. These patients demonstrate signs and symptoms of right heart failure. Dyspnea and fatigue may be present at rest. Symptoms are increased by any physical activity.

Modified from Galie N, Hoeper HM, Humbert M, et al. Guidelines for the diagnosis and treatment of pulmonary hypertension. *Eur Heart J* 2009;30:2493–2537.

Leisure Activities and Activities of Daily Living

Because of the broad range of symptoms and the unpredictable risk of sudden death in many of these patients, it is very difficult to make any generalized recommendations regarding physical activity in this population. With rare exceptions, activity should be of low intensity and have both a low dynamic and static requirement (see Table 6.8). In more symptomatic patients, a formal exercise prescription may be useful (161). These patients may be quite deconditioned and their quality of life may be significantly improved by simple activities designed to improve their musculoskeletal conditioning. This may initially need to be in a structured and monitored location rather than a home-based program. Regardless of the level of activity, frequent reassessment is necessary in all patients. Exercise recommendations may be liberalized or restricted based on the patient's clinical course (160). There has been a very significant improvement in the clinical course of patients with PHT over the last decade as a result of treatment with several new classes of therapeutic agents. Many patients will have a marked improvement in the symptoms with onset of therapy. For this reason, the need to frequently reassess exercise capacity and recommendations in this population cannot be overemphasized (160).

Most of the recommendations of PAH also apply for patients PHT from Eisenmenger Syndrome. Exercise capacity is often limited by both cardiac and peripheral factors (160,162). However, as stated above, these patients are at less risk for sudden drops in systemic cardiac output and blood pressure. Exercise-related SCD appears to be significantly less common compared to patients with PAH. This would suggest that if these patients can tolerate somewhat more vigorous physical activity, it may be undertaken with less risk. Careful and frequent monitoring of exercise symptoms and capacity are still essential (160).

Competitive Sports

Given the high-risk nature of this population, restriction from any competitive sport is probably warranted. Special circumstances may occur when participation in low static and dynamic sports may be considered on an individual basis for Class 1 patients. There are, however, no significant data that would allow accurate assessment of risk for an individual patient.

Heart Transplantation

Exercise capacity as measured by both aerobic capacity and musculoskeletal strength is significantly decreased in the pediatric population following heart transplantation. The causes of these limitations are multifactorial. The few reports of exercise

testing in pediatric heart transplant patients have reported aerobic capacities, as measured by maximal VO_2 , of 50% to 60% of healthy age and sex matched peers (163–165). These values are not significantly different from those reported in the adult population. The reasons for this finding appear to be due to both central and peripheral factors combining to impair aerobic capacity. Especially in early posttransplant periods, stroke volume is limited. This may be due to systolic impairment but more importantly to diastolic dysfunction with high cardiac filling pressures. Abnormalities of autonomic innervation and function also impact on cardiac output during exercise. At least initially there is a loss of autonomic innervation to the heart. This significantly decreases chronotropic reserve and blunts the time course of the chronotropic response. There is some evidence for reinnervation and improved chronotropy late after transplant in some patients or as a response to cardiac training (discussed below). In addition to the cardiac effects, autonomic tone is abnormal in the peripheral vasculature. Brachial reactivity is impaired and systemic vascular resistance is increased (166–169).

Limitations of the peripheral exercising musculature are most likely at least as important as central mechanisms in limiting aerobic capacity. Following heart transplant, skeletal muscle mass is often reduced by 20% of normal. Capillary density is also significantly decreased. This may reflect the marked deconditioning in these patients that occurs prior to transplantation but may also be the result of immunosuppressant therapy. These changes result in an impaired ability of the exercising muscle to extract oxygen. Muscle strength is significantly impaired, especially in the early transplant period. Bone demineralization is a frequent finding. This may result in stress and compression fractures. Use of ongoing immunosuppressant medications may continue to exacerbate the problem of demineralization.

Serial studies of exercise performance following pediatric heart transplants are limited. Recent studies of Davis et al. (163) and Dipchand et al. (165) are conflicting. Both show early improvement in aerobic capacity and working capacity. Davis saw a decline of improvement after about 3 years while Dipchand's population remained steady with some patients showing a decrease associated with the onset of graft vasculopathy. The reason for these findings are unclear but are probably the combined improvement of systolic and especially diastolic function in the immediate posttransplant period as well as the longer term improvement in musculoskeletal conditioning, even in the absence of formal rehabilitation. In addition, improved chronotropy suggests at least some patients benefit from autonomic reinnervation of the donor heart.

TABLE 6.8

Recommendations Following the F.I.T.T. Principle for Recreational Activities and Exercise Training in Children and Adolescents with Pulmonary Hypertension^a

F.I.T.T.	Cardiovascular (dynamic) Training	Muscle (static) Training
Frequency	3–5×/wk	3–5×/wk
Intensity	Low intensity: 20%–40% of max VO_2	Low: 20% of MVC
Time	60 min per session	Included in cardiovascular training session
Type	Predominantly dynamic activity: e.g., walking either on a treadmill or an open course.	Major muscle groups, upper, and lower limbs and torso. Exercise aims at correct technique and breathing pattern to avoid the Valsalva maneuver.

VO_2 , minute oxygen consumption; MVC, maximum voluntary contraction.

^aIf the patient is WHO Class II or greater, formal exercise testing and prescription should be considered to assign intensity and types of activities.

Evaluation Prior to Exercise and Sports Participation

Like patients with PHT, those who have undergone heart transplantation represent a unique population. They should be evaluated for physical activity by physicians and health care providers who have specialized knowledge in this area. Assessment of systolic and diastolic function by echocardiography and cardiac catheterization is routine in this population and should be a part of any preparticipation evaluation. As the period of time from transplantation lengthens, the risk for development of graft dysfunction and, most importantly, coronary graft vasculopathy increases. Routine exercise testing, myocardial perfusion imaging, and even selective coronary angiography are essential parts of screening to assure safe participation in physical activity.

Unlike many congenital cardiac conditions, following heart transplantation, noncardiac medical issues may be just as important as cardiac functioning in determining the ability to perform certain activities. Muscle mass loss and deconditioning, bone mineral loss, and other end-organ dysfunction are all potentially important factors to assess especially in the early posttransplant period. These children usually benefit from exercise testing and a thorough physical therapy evaluation. Often a structured rehabilitation program that transitions to a home activity program is desirable for newly transplanted patients.

Leisure Activities and Activities of Daily Living

There are no evidence-based studies assessing the types, safety, or benefit of sports and exercise participation in children following heart transplantation. In a very small interview study of mixed solid organ transplant patients, Olausson et al. (170) reported that most expressed the opinion that they lived normal lives. Ross et al. (171) reported on the long-term survival of a cohort of pediatric heart transplantation patients at 10 and 20 years after transplant. They state that “physical rehabilitation and return to normal lifestyle has been nearly 100%.” They cite two anecdotal cases of patients participating in vigorous competitive sports. In an editorial, Fricker (172) listed a series of recommendations for pediatric heart transplantation patients:

1. Exercise should be encouraged, not discouraged.
2. All patients should be in a monitored rehabilitation program within 3 months following transplantation.
3. Return to age-appropriate activities including physical education class within 6 months after transplantation.
4. Endurance activities will be better tolerated than intermittent high-intensity activity.
5. Participation in competitive sports should be individualized with detailed yearly reevaluation of participation.

Absent any studies on leisure activity in this population, this appears to be a reasonable approach. Patients with no evidence of graft vasculopathy, other musculoskeletal problems, or end-organ dysfunction should be encouraged to engage in vigorous recreational activity (see Table 6.9).

Competitive Sports

There is an equal lack of data in the adult and pediatric populations regarding competitive sports participation following heart transplantation. A number of case reports and small studies show that heart transplant recipients can train and compete often quite successfully in vigorous athletic activity. However, the numbers in these studies are too small to allow generalization to the entire transplant population regarding the safety and benefits of such training. Given these limitations, the recommendations from the 36th Bethesda Conference on Eligibility Recommendations for Competitive Athletes with Cardiovascular Abnormalities are probably appropriate (173):

1. Because of special issues involved with transplant patient management, decisions as to the feasibility of athletic competition for cardiac transplant recipients should be made in conjunction with the patient's transplant cardiologist.
2. Athletes with no coronary luminal narrowing, no exercise-induced ischemia, and normal exercise capacity for age can generally participate in all competitive sports as appropriate for their exercise capacity.
3. Athletes with coronary luminal narrowing should be risk stratified as outlined in the recommendations by Thompson et al. (173).

In the absence of any better data, these recommendations are probably a good basis, at least, for the evaluation of the adolescent population as well.

DEFECTS THAT ARE ASSOCIATED WITH SUDDEN CARDIAC DEATH IN ATHLETES

Congenital Coronary Artery Abnormalities

The congenital coronary anomalies in which there is often an increased risk of myocardial ischemia and SCD are those in which the anomalous vessel arises from the inappropriate

TABLE 6.9

Recommendations Following the F.I.T.T. Principle for Recreational Activities and Exercise Training in Children After Heart Transplantation without Coronary Artery Disease

F.I.T.T.	Cardiovascular (dynamic) Training	Muscle (static) Training
Frequency	3–5×/wk	3–5×/wk
Intensity	Moderate to Heavy: near VAT (55%–65% of max $\dot{V}O_2$).	Moderate: 20%–50% of MVC
Time	60 min per session	Included in cardiovascular training session
Type	Predominantly dynamic activity: e.g., walking, jogging, running, cycling, running games	Major muscle groups, upper, and lower limbs and torso. Exercise aims at correct technique and breathing pattern to avoid the Valsalva maneuver.

$\dot{V}O_2$, minute oxygen consumption; MVC, maximum voluntary contraction; VAT, ventilatory anaerobic threshold.

Modified after McBride MG, Binder TJ, Paridon SM. Safety and feasibility of inpatient exercise training in pediatric heart failure: a preliminary report. *J Cardiopulm Rehabil Prev* 2007;27(4):219–222.

sinus of Valsalva and courses intramurally between the aorta and pulmonary artery, with the anomalous left coronary artery from the right sinus carrying the greatest risk of SCD. Indeed, these anomalies are the second leading cardiovascular cause of SCD in young athletes in the United States (25). Identification of coronary anomalies is challenging because many individuals do not experience warning symptoms. The first symptom may be SCD. A screening ECG is almost always normal in these patients. In those who complain of *exertional* chest pain, palpitations, dizziness, presyncope, or syncope, the presence of an anomalous coronary artery must be considered. Transthoracic echocardiography with color Doppler should be performed to demonstrate coronary anatomy. When an anomalous coronary artery is suspected, confirmatory imaging such as cardiac MRI, ultrafast CT, and occasionally coronary angiography are almost always utilized. In those for whom the left main coronary arises aberrantly, surgery is usually indicated. The management of asymptomatic patients with anomalous right coronary artery has not been defined, with some opting for surgery and others opting for medical management, including exercise restriction. The relative risks and benefits of surgical versus nonsurgical management of these defects are far from clear.

Evaluation Prior to Exercise and Sports Participation

Children with congenital coronary anomalies should have a baseline physical examination and ECG, and a resting echocardiogram to delineate coronary anatomy, evaluate heart function, assess atrioventricular and aortic valve regurgitation, and assess resting wall-motion abnormalities. A maximal graded exercise stress test, usually with nuclear myocardial perfusion and/or stress echocardiography should be performed. Besides measuring aerobic and physical working capacities, the stress test will help assess for evidence of ischemia, exercise-induced symptoms, and exercise-induced arrhythmias. A Holter monitor is useful to evaluate for arrhythmias.

Leisure Activities and Activities of Daily Living

If maximal graded exercise testing and other provocative testing are normal, most practitioners would encourage asymptomatic children and young adults with anomalous right

coronary artery from the left sinus of Valsalva to participate in leisure sports and daily physical activities (174). Regular recreational activities of at least moderate aerobic intensities should be encouraged (see Table 6.10). Static training should be at a moderate level as well. Those who have exertional symptoms, evidence of ischemia on provocative testing, and those with anomalous left coronary artery from the right sinus of Valsalva should refrain from recreational activities until further treatment, likely surgery.

Competitive Sports

The current guidelines in the United States recommend exclusion from competitive sports once the diagnosis of anomalous coronary artery has been confirmed (76). If the patient undergoes surgery, the Bethesda guidelines allow for full participation in competitive sports 3 months after a successful operation, as long as there is no evidence of ischemia, ventricular tachycardia, or ventricular dysfunction during a maximal graded exercise stress test (76). An imaging study during exercise, such as nuclear myocardial perfusion and/or stress echocardiography may be helpful in evaluating postoperative ischemia in addition to the exercise stress test. There are no long-term data addressing the effectiveness of surgery in reducing risk of SCD in this population.

Acquired Coronary Disease

Kawasaki Disease

Kawasaki disease is the most common cause of acquired heart disease in children in the United States (175). Ischemic heart disease that can lead to myocardial infarction and SCD can occur due to coronary aneurysms, together with progressive coronary artery stenosis (176). The risk of SCD due to extent of CAD appears to change over time. For the first 20 years after the onset of Kawasaki disease, patients without evidence of coronary aneurysm or with initial transient dilation on echocardiography appear to have no greater risk for ventricular tachyarrhythmias and SCD than that of the general population (176). Those with aneurysms that regress to normal lumen diameter may have persisting structural and functional coronary abnormalities (176). Suda and colleagues recently reported the long-term prognosis (median 19 year follow-up)

TABLE 6.10

Recommendations Following the F.I.T.T. Principle for Recreational Activities and Exercise Training in Children and Adolescents with Coronary Anomalies and Acquired Coronary Disease

F.I.T.T.	Cardiovascular (dynamic) Training	Muscle (static) Training
Frequency	Moderate: daily Vigorous: $\geq 3\times/\text{wk}$	$\geq 3\times/\text{wk}$
Intensity	Moderate: 55%–60% of max VO_2 to heavy (below 80% of max VO_2)	Moderate: 20%–50% MVC
Time	Most of daily ≥ 60 min activity	As part of daily ≥ 60 min activity
Type	Predominantly dynamic activity: e.g., running, jumping, cycling, swimming, inline skating, skateboarding, soccer	Predominantly static activity: e.g., gymnastics, climbing, push-ups, martial arts, ball sports practice

VO_2 , minute oxygen consumption, MVC: maximum voluntary contraction.

These recommendations apply to those patients with no evidence by history or testing of exercise-induced myocardial ischemia and no coronary artery stenosis* Patients with anomalous left coronary artery, even if asymptomatic, should refrain from physical activity until after surgical repair.

of patients with giant coronary aneurysms that did not regress and, instead, remodeled over time, leading to intimal thickening and risk of ischemic heart disease. Of the 76 patients initially followed, 7 died and 1 underwent heart transplantation. In addition, there were numerous catheter and surgical coronary interventions with cumulative coronary intervention rates of 28%, 43%, and 59% at 5, 15, and 25 years after disease onset, respectively (177). Certainly, in patients with Kawasaki disease, risk associated with physical activity and exercise depends on the degree of coronary involvement. Paridon et al. (178) reported on 46 children and adolescents with a history of Kawasaki disease and showed that maximal oxygen consumption was within normal limits without a difference based on coronary artery status (i.e., none, regressed, or current aneurysms). Another study focusing on children with persistent coronary aneurysms also showed normal peak oxygen consumption, workload, and anaerobic threshold when compared to control subjects (179).

Evaluation Prior to Exercise and Sports Participation

Children with Kawasaki disease should have, in addition to a physical examination and ECG, a resting echocardiogram to evaluate heart function and presence and size of coronary aneurysms. A maximal graded exercise test in conjunction with nuclear myocardial imaging and/or stress echocardiography can be helpful in assessing evidence of ischemia, wall-motion abnormalities, and presence of exercise-induced arrhythmias.

Leisure Activities and Activities of Daily Living

Because of the overall cardiovascular benefits associated with physical activity and exercise, it is recommended that all patients with Kawasaki disease remain physically active and avoid a sedentary lifestyle (76). Regular recreational activities of at least moderate level should be encouraged daily. Static training should be at least at a moderate level as well (see Table 6.10).

Competitive Sports

For competitive athletics, the risk is dependent on coronary artery status. The following recommendations are from the 36th Bethesda Conference guidelines for competitive athletes (76). Those patients without coronary artery abnormalities or transient coronary artery ectasia may participate in all sports after 6 to 8 weeks from disease onset. Similarly, those with regressed aneurysms can participate in all competitive sports as long as there is no evidence of exercise-induced ischemia using exercise stress testing with myocardial perfusion imaging. For those patients with isolated small- to medium-sized aneurysms in one or more coronary arteries without exercise-induced ischemia or arrhythmia and with normal left ventricular function are thought to be at low risk for ischemia. They may participate in low to moderate static and dynamic competitive sports (class IA, IB, IIA, and IIB) (see Fig. 6.1). Ischemia evaluations using exercise stress testing with myocardial perfusion imaging should be repeated at 1- to 2-year intervals.

Patients with at least one large coronary aneurysm, multiple (segmented), or complex aneurysms with or without obstruction to coronary artery blood flow may participate in class IA and IIA sports in the absence of reversible ischemia and exercise-induced arrhythmias on exercise stress testing and normal left ventricular function. Annual exercise stress testing with myocardial perfusion imaging should be performed to monitor the development of ischemia.

Patients with recent myocardial infarction or revascularization should not participate in competitive sports until their recovery is complete, which is usually 6 to 8 weeks. After their recovery, those with normal left ventricular function and exercise tolerance and absence of reversible ischemia on myocardial perfusion testing, and exercise-induced arrhythmias may participate in class IA and IB sports. Those with left ventricular ejection fraction <40%, exercise intolerance, or exercise-induced ventricular tachyarrhythmias should not be allowed to participate in competitive sports. As well, patients who are taking anticoagulants and/or antiplatelet drugs (aspirin, clopidogrel) should not participate in sports that pose danger of high-speed collision.

Atherosclerotic Coronary Artery Disease

Atherosclerotic CAD is the primary cause of exercise-induced SCD in adults older than 35 years, with those who are habitually sedentary at highest risk (115). In younger athletes (i.e., <35 years old), acute exercise-related ischemia is rarely caused by CAD, except in those with dyslipidemias that place them at high risk for premature atherosclerosis. The most common dyslipidemias in children and young adults are: heterozygous familial hypercholesterolemia, familial defective apoB100, polygenic hypercholesterolemia, familial combined hyperlipidemia, and familial hypertriglyceridemia. Patients with these dyslipidemias seldom have manifest CAD in childhood or young adulthood. As well, those with obesity-related dyslipidemia almost never develop atherosclerotic CAD during childhood and young adulthood. For those patients with extremely rare genetic dyslipidemias (i.e., homozygous familial hypercholesterolemia or sitosterolemia), risk of premature CAD is significantly increased during childhood and young adulthood.

The diagnosis of atherosclerotic CAD is made by having any of the following: history of myocardial infarction, history suggestive of angina pectoris in conjunction with evidence of inducible ischemia, and/or coronary atherosclerosis demonstrated using coronary imaging (173). In general, for people at risk for developing CAD, a sedentary lifestyle increases risk, whereas physical training reduces the risk of SCD during exercise (115).

Evaluation Prior to Exercise and Sports Participation

Most patients with the common genetic dyslipidemias and those with lifestyle-related hypercholesterolemia need little evaluation beyond routine care, including a physical examination, by the primary care pediatrician. These children do not manifest CAD at a young age and should not need further imaging studies performed. Patients with the rare genetic dyslipidemias, such as homozygous familial hypercholesterolemia, should have in addition to a physical examination and ECG, an annual resting echocardiogram to evaluate heart function and for aortic valve disease. Maximal graded exercise stress testing should be considered in adolescence, especially those with aortic valve regurgitation on echocardiography. If there are abnormalities noted on the exercise stress test, coronary angiography should be performed especially if there is high suspicion of atherosclerotic disease based on echocardiographic findings and worrisome family history (180). Electron beam computerized tomography may be useful in evaluating atherosclerosis, but this technology has not been adequately studied in children.

Leisure Activities and Activities of Daily Living

In the absence of evidence for exercise-related myocardial ischemia or laboratory evidence of more than mild coronary artery stenosis, regular recreational activities of vigorous to moderate levels should be encouraged daily. Static training

should be at a moderate level as well (see Table 6.10). Indeed, regular physical activity and recreational sports should be encouraged in patients at risk for and with CAD as this helps improve overall cardiovascular health (173). Those who have had a recent myocardial infarction or myocardial revascularization should not participate in physical activity until recovery is complete. These patients would likely benefit from cardiac rehabilitation as part of their recovery (173).

Competitive Sports

There is a lack of data on the presence and severity of CAD in competitive athletes. For this reason, the Bethesda conference guidelines are based on adult data from nonathletes with CAD, with two levels of risk assigned based on testing (173). It is likely that the risk of an exercise-related event increases with both the intensity of the competitive sport as well as the severity of disease in the athlete himself. Those with mildly increased risk are defined as: preserved left ventricular systolic function at rest (i.e., ejection fraction > 50%), normal exercise tolerance for age, absence of exercise-induced ischemia or complex ventricular arrhythmias, absence of hemodynamically significant stenosis (>50% luminal diameter narrowing) by coronary angiography, and/or successful myocardial revascularization. Those considered at substantially increased risk exhibit any of the following: impaired left ventricular systolic function at rest (i.e., ejection fraction < 50%), exercise-induced myocardial ischemia or complex ventricular tachyarrhythmias, or hemodynamically significant coronary arterial stenosis by coronary angiography. Based on these definitions, the recommendations are for those in the mildly increased risk group to participate in low dynamic and low/moderate static competitive sports (classes IA and IIA) but not in highly competitive activity. However, in those with very low exercise risk, select athletes may be allowed to compete in higher intensity sports. Also, these recommendations are not for children with dyslipidemias and no evidence of CAD (e.g., the vast majority of children with lipid abnormalities). This group should be treated as other healthy children and not be restricted from competitive athletics. Athletes in the substantially increased risk group should be restricted to low-intensity competitive sports (class IA).

Once CAD is established, it is necessary to stress that even in those athletes for whom risk is only mildly increased, competitive exercise may transiently increase the risk of an exercise-related adverse event.

Hypertrophic Cardiomyopathy

HCM is the leading cause of SCD in U.S. athletes and can have variable phenotypes. Four major phenotypes have been described and it is important to recognize that SCD can occur in all. Most patients have inherited cardiomyopathy due to mutations in sarcomeric protein genes, and gene tests to identify these mutations are readily available but expensive. Some patients who are genotype positive but phenotype negative may have myocardial disarray and disorder prior the development of clinically detectable hypertrophy (181-183). Patients who are genotype positive without clinically detectable hypertrophy can be of any age but are usually younger than 14 years (184,185). The risk of SCD in genotype positive but phenotype negative patients appears to be lower compared to phenotype positive individuals. Numerous screening programs to detect HCM have been attempted. The high cost of testing, the low prevalence rate (1 in 500 in adults, likely lower in children) and subsequent low detection rate, and the possibility of inappropriate disqualification of competitors with athlete's heart makes universal screening problematic.

Evaluation Prior to Exercise and Sports Participation

All athlete candidates require a careful medical history with particular attention to a history of syncope or dizziness during athletic competition, dyspnea with exertion, angina, and palpitations. Family history may include sudden death in members <40 years, a finding that should prompt the examiner to consider inherited types of cardiac disease. Systolic murmurs that are louder in the standing position after squatting may alert the examiner to dynamic outflow tract obstruction. ECGs are abnormal in approximately 90% of affected individuals. Echocardiography typically identifies affected individuals, but mild hypertrophy may mimic athlete's heart. Diastolic dysfunction due to myocardial disarray can be detected utilizing Doppler tissue imaging and may predate significant hypertrophy. Gene testing can identify young family members who have no ostensible expression of the disease. In the absence of gene testing, family members of affected individuals should have ECG and echocardiographic screening every few years until adolescence at which time annual screening is suggested.

Leisure Activities and Activities of Daily Living

Asymptomatic patients should pursue a healthy lifestyle, be allowed to regulate their own activities, rest when fatigued, and maintain hydration. Intravascular volume depletion worsens dynamic outflow tract obstruction and should be avoided. Electrolyte disturbances that may result from dehydration likely increase the risk of malignant arrhythmias. Isometric activities should be kept to a minimum.

Competitive Sports

Athletes with a probable or definitive diagnosis of HCM should be excluded from all but low-intensity sports, irrespective of age and gender and cardiac phenotype. Asymptomatic athletes with phenotype negative, genotype positive cardiomyopathy without a family history of SCD may participate in all competitive sports. At the time of this writing, there are no convincing data that these patients are at risk of a sudden catastrophic event as a result of vigorous exercise. Until such data exist, there appears to be no compelling evidence that would preclude these individuals from athletic competition.

Asymptomatic patients with implantable cardioverter-defibrillators should not engage in athletic competition, with the exception of low-intensity sports. Sports with danger of bodily collision in this setting should also be avoided. The availability of external cardioverter-defibrillators does not change the above recommendations at the time of this writing. However, it is expected that present day studies may alter recommendations for patients with HCM who have external or internal cardioverter-defibrillator availability.

Other Cardiomyopathies

Less common cardiomyopathies include dilated, restrictive, or mixed physiology. These cardiomyopathies arise from a variety of etiologies, such as genetic, chemical or toxic, and postinfectious. Exercise performance in this population may vary from severely limited to normal depending on the degree of ventricular dysfunction. Because of the heterogeneity of these diseases it is not possible to make generalized recommendations regarding physical activities and sports participation.

Limited data on exercise ability are available in some of these groups. Patients who have received anthracycline therapy as part of a chemotherapeutic treatment may develop a slowly progressive, dose-dependent, dilated cardiomyopathy as children or young adults. Exercise performance may be normal in patients who are only mildly affected and this may remain stable for many years (186,187). However, symptoms

will frequently occur in patients with significant, progressive decline in cardiac function. The presence of a restrictive physiologic component especially in the presence of PHT may greatly increase the risk in these postanthracycline population.

Noncompaction cardiomyopathy is a relatively newly recognized entity (188,189). The incidence of this type of cardiomyopathy is unknown. Patients may present with severe heart failure but are often completely asymptomatic and identified by an echocardiogram performed for an unrelated cause. For this reason, the risk for exercise in this population is largely unknown.

Evaluation Prior to Exercise and Sports Participation

Because of the heterogeneity of this group, each patient should be evaluated by a clinician familiar with the type of cardiomyopathy. ECGs and Holter monitors are useful to assess for the presence of arrhythmias. Echocardiograms are useful to assess systolic and diastolic function, as well as the presence of noncompaction, and monitor the development of PHT. More specific assessment of the myocardium and its function may be needed using testing such as MRI in certain cases. Exercise testing should be performed to assess aerobic and physical working capacity, evaluate incidence of arrhythmias, and symptoms suggestive of an inability to maintain cardiac output with increasing exercise intensity.

Leisure Activities and Activities of Daily Living

As stated above, the high degree of heterogeneity in this population precludes any meaningful generalized statements concerning leisure physical activity. However, almost all of the patients will benefit from routine physical activity of some type. Quality of life and physical working capacity have been shown to be improved in adults by routine exercise programs even in patients with advance heart failure (21). There are much less data for children but these also suggest that physical conditioning can be improved in severely symptomatic patients (190). Highly structured rehabilitation is not needed in most mild cases, although a formal exercise prescription is often useful to help guide the patient's activities. Often, little or no restrictions on leisure or daily living activities are needed in most mildly affected cases.

Competitive Sports

There are no data on risk stratification for competitive sports in the pediatric cardiomyopathy population. As a consequence, restriction from all but low static and dynamic activities appears to be a reasonable default approach. Individual exceptions to this approach may be warranted in rare very mild cases where testing would suggest that the risk for sudden death is low, and normal or high physical working capacity and aerobic capacity are preserved.

Arrhythmias and Cardiac Channelopathies

Approximately one-third of all SCDs occurring during athletic activities in the pediatric and young adult age range are not associated with any evidence of structural heart disease or cardiomyopathy (25). These deaths are most likely due to arrhythmias. Defects in the cardiac sodium and potassium channels are those most associated with SCD during athletics. These include long QTc syndrome and Brugada Syndrome. The evaluation of these defects and their risk of SCD are discussed in a separate chapter (see Chapter 16).

Systemic Hypertension

Systemic hypertension is the most common cardiovascular problem diagnosed in adolescent and young adult athletes. As

was stated at the beginning of this chapter, there is an epidemic of obesity in the pediatric and adolescent population. This is translating into a growing number of cases of essential hypertension in the pediatric age range (191,192). Fortunately, this is one of the few cardiovascular abnormalities where exercise and competitive sports are not only often safe but may be beneficial in its control. Certainly, data from young adults suggest that vigorous dynamic and resistance exercise results in prolonged lowering of blood pressure and reduction in the likelihood of developing essential hypertension.

Evaluation Prior to Exercise and Sports Participation

Evaluation for hypertension should conform to the guidelines of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents (193). Especially in preadolescent patients, secondary causes of hypertension that may impact on eligibility to compete should be carefully evaluated.

Leisure Activity and Activities of Daily Living

All patients with systemic hypertension should be encouraged to participate in regular vigorous recreational activities as part of treatment for their hypertension. Patients with Stage 1 hypertension and no end-organ damage (including increased left ventricular mass) should be encouraged to engage in routine moderate to high dynamic and static activities similar to those patients with well-repaired CHD and no exercise restrictions (Table 6.2). Care may be needed if these patients have metabolic syndrome and significant obesity. An exercise evaluation and prescription may be needed in these cases to avoid the risk of orthopedic injuries when undertaking a vigorous new unsupervised activity program.

Patients with more severe hypertension, Stage 2, and certainly patients with evidence of increased left ventricular mass, should have appropriate control of their hypertension. Once the hypertension is controlled, these patients should also be encouraged to engage in regular recreational activity as part of their hypertension management.

Competitive Sports

Patients with Stage 1 hypertension and no cardiac or other end-organ abnormalities can and should be encouraged to participate in competitive sports. Blood pressure should be monitored routinely after beginning competition. Patients with Stage 2 hypertension should not participate in competitive sports until the hypertension is controlled and there is no evidence of cardiac or other end-organ damage.

The ability to perform work or to exercise is a basic function of life, and many disease states affect this ability. Children are, or ought to be, by nature, physically active whether in spontaneous school yard play or in any number of organized activities. Accurate and reproducible measurement of work performance or exercise capacity provides a means to quantify a dimension of disease severity and assess one aspect of quality of life; to assess the effects of treatment and training; and, in some instances, to identify previously unrecognized disease. Despite a proliferation of noninvasive measurement techniques, much of our knowledge of exercise physiology still comes from studies in adults. Thus, the field of pediatric work physiology has had to draw many conclusions by extrapolation from these studies, an inherently flawed approach that readers must bear in mind.

BASIC EXERCISE PHYSIOLOGY

Work, Energy, and Power

Exercise involves utilization of energy and its transformation into mechanical work. Because work equals force multiplied by distance, the unit for work is the newton-meter, or joule (J). There is a constant relationship between energy and work as described by the relationship one kilocalorie (kcal) being equal to 4.1868 joules (J). Power is work performed per unit time, expressed as joules/second, but commonly referred to as watt (W) ($1 \text{ W} = 1 \text{ J/s}$). Older nomenclature used the kilopond-meter (kpm), where one kilopond is the force acting on a 1 kg mass at the normal *G*-force (on earth), such that $1 \text{ W} = 6.12 \text{ kpm/min}$.

From the mechanical perspective, there are two types of exercise: isotonic (dynamic) and isometric (static). Isotonic exercise implies alternate rhythmic contraction and relaxation of muscles against resistance. Isometric exercise involves muscular contraction against a fixed resistance with little (if any) muscle shortening. Clinical exercise testing can be done using either isotonic or isometric exercise. Usually, however, clinical exercise testing is done using isotonic forms of exercise, such as cycling, walking, and running. From the energetics perspective, the chemical energy required to perform work can arise from aerobic or anaerobic sources. Use of oxygen is a major contributor to ATP synthesis in light to moderate exercise regardless of duration: so-called aerobic exercise. In contrast, short sprints, or heavy isotonic and isometric exercise, can be accomplished without oxygen, at least for brief periods. In anaerobic exercise, muscle energy is supported by the phosphocreatine (PCr)-ATP system followed by glycolysis, not through mitochondrial oxidative phosphorylation that requires oxygen consumption. However, in real life it is exceedingly unlikely that such a dichotomy exists when a child plays in fits, starts, and stops, which typically characterize

daily play. During incremental exercise, one can observe—and many have investigated—a level of work or intensity of exercise below which one allegedly accomplishes aerobically and above which one continues anaerobically, or at least anaerobic energy sources predominate. Many of these conclusions have been reached by gas-exchange analysis or measurement of blood lactate levels. More recent results employing near-infrared spectroscopy (NIRS) paint a different picture—one demonstrating an early, continuous, but complementary role of anaerobic metabolism to the primacy of aerobic metabolism during exercise. Because energy is necessary to perform work and requires combustion of oxygen, there is a predictable relationship between aerobic work and oxygen consumption or uptake ($\dot{V}\text{O}_2$) as shown in Figure 7.1. This approximates 10 mL O_2 per minute per watt in normal, healthy adults (1,2) but oxygen cost of work (mechanical efficiency) tends to be higher in children and is somewhat age dependent (3).

If one excludes so-called tests of anaerobic capacity such as Wingate, exercise testing strategies have evolved over the past century from classical steady-state procedures, incremental or otherwise, to non-steady-state procedures. The latter have largely supplanted the former, and increments can be discrete (e.g., 1 to 2 minutes each) or continuous, also known as ramp protocols. The difference between steady-state and non-steady-state exercise can best be understood by considering energy utilization at onset of exercise. If one were to immediately change from walking to running on a treadmill, or unloaded pedaling to 50 W on a cycle ergometer, work rises in an instant but $\dot{V}\text{O}_2$ does not rise nearly so quickly. This step-up in power requires adjustments to ventilation and cardiac output in order to meet the energy requirement to perform the additional work. Until the cardiopulmonary system adapts to this increment, the exercising muscles utilize anaerobic energy sources such as ATP and PCr replenished by rate-limiting glycolytic pathways. In doing so, the exercising muscles incur an O_2 debt, which is simply the area under the curve shown in Figure 7.2. Once the cardiopulmonary system has made the necessary transition in terms of ventilation and cardiac output, such that energy required to perform the additional work can be provided aerobically, exercise is considered steady state. The time course of the rise to steady state is described by a time constant (τ), and mathematically it can be shown that steady state is achieved over a time equal to approximately five to six time constants. The term exercise “kinetics” has been coined to describe this transition process. Time constants for heart rate (HR) and $\dot{V}\text{O}_2$, but not for cardiac output, have been reported in children and, in general, are shorter (smaller) compared to those in adults (4,5). The distinction becomes an important consideration should one attempt to apply certain physiologic principles, such as solving the Fick equation, to non-steady-state exercise measurements. In general, measurements such as cardiac output that employ solving the Fick equation, or measurement of physiologic dead space by the Bohr equation, should be based on measurements done

Figure 7.1. Diagrammatic illustration of the relationship between oxygen consumption and workload. (From Godfrey S. *Exercise Testing in Children*. London, UK: WB Saunders Co. Ltd., 1974, with permission).

during steady-state exercise. That does not necessarily mean that non-steady-state measures of such parameters are invalid but simply that they should be interpreted with caution. It has been amply demonstrated that many measurements made during non-steady-state, progressive exercise provide results or values very similar to those made during conventional, steady-state, tests. This is one reason, other than practicality,

Figure 7.2. Schematic plot showing rest-work transition, plotting oxygen uptake versus time, in order to illustrate two concepts: (i) oxygen deficit, that is, $\dot{V}O_2$, which would be required if all metabolic requirement to perform work were met instantaneously by aerobic mechanisms, and (ii) time constant (τ , seconds), which is the time required to reach 50% of the plateau value. As a rule, the plateau is reached in the equivalent time of five to six time constants.

that non-steady state, incremental, or ramp exercise protocols largely have replaced the classical steady-state methods.

Exercise requires a complex and intricate interaction of multiple organ systems, and abnormalities in any of these organ systems will affect and potentially limit performance. The four principal systems involved in transferring oxygen from the atmosphere to the myocyte mitochondria—lungs, heart, blood, and muscle—are intimately linked in series and overall transport and utilization of oxygen depends on all components functioning optimally and in concert. When any one of these organ systems reaches maximal functional capacity, further exercise will be limited. An exercise test has the potential to reveal the limiting organ system by applying the engineering principle of stress testing, rather than providing a specific diagnosis in a patient presenting with exercise intolerance. A more fundamental approach is to ask whether oxygen supply (pulmonary/cardiovascular/blood transport), oxygen utilization (substrate availability, enzyme function) independent of oxygen supply, or converting chemical into mechanical energy (muscle efficiency) imposes the limiting factor for maximum work capacity. In health, the scale tips toward oxygen supply as the limiting step; thus, the circulatory system and specifically total oxygen transport capacity—product of cardiac output and O_2 carrying capacity ($\dot{Q}O_2$)—become the factor limiting performance. In a maximal exercise test to voluntary exhaustion, most healthy subjects cease exercise because of leg discomfort or fatigue, though some will complain of dyspnea, as the reason(s) for being unable to continue. This presumably reflects leg muscle fatigue, where O_2 demand exceeds O_2 supply to (or utilization by) muscle mitochondria.

Maximal-Aerobic Power

Many different indices can be used to describe fitness or maximal exercise capacity. The amount of work a person can perform could be used to define exercise capacity but maximum aerobic power or maximum oxygen uptake ($\dot{V}O_{2\max}$) achieved during exercise is probably the best index. $\dot{V}O_{2\max}$ is defined by a plateau in $\dot{V}O_2$ that occurs despite continued exercise, proof that work can be performed using anaerobic energy production, but the amount that can be performed anaerobically is limited. This concept evolved using discontinuous, quasi-steady-state, exercise protocols nearly a century ago. A plot of $\dot{V}O_2$ versus work will reach an asymptotic $\dot{V}O_2$ if and only if the subject is able and willing to continue exercise, making it crucial to ensure that a subject's effort is maximal in order to properly determine $\dot{V}O_{2\max}$. It is difficult to motivate untrained subjects and most children to exercise to that asymptotic $\dot{V}O_2$, as continuing becomes intolerable such that a plateau is seldom observed in children. Thus, the concept of $\dot{V}O_{2\max}$ has given way to the more practical " $\dot{V}O_{2\text{peak}}$ ". The terms $\dot{V}O_{2\text{peak}}$ or peak work capacity have been coined to refer to a symptom- or discomfort-limited clinical exercise test, also known as voluntary exhaustion. In practice, there is little or no difference between $\dot{V}O_{2\text{peak}}$ and $\dot{V}O_{2\max}$ (6,7).

Maximum cardiac output is closely correlated with maximum oxygen uptake, although this concept continues to be the subject of debate among exercise physiologists (8). Oxygen supply to the exercising muscle is determined by oxygen carrying capacity (a function of hemoglobin) and rate of transport from the cardiopulmonary source to its destination, that is, cardiac output. This can be expressed mathematically as the product of cardiac output and oxygen content of the blood, or $\dot{Q}O_2$. It follows that reductions in cardiac output (and hemoglobin level) will reduce $\dot{V}O_{2\max}$; conversely, experimentally increasing $\dot{Q}O_2$ will raise $\dot{V}O_{2\max}$ (9,10). Exercising larger (as opposed to smaller) muscle groups or more (vs. fewer) muscle

groups will result in higher $\dot{V}O_{2\max}$. Higher $\dot{V}O_{2\max}$ can be best achieved by treadmill exercise than by cycle exercise because more muscle groups are working when one performs treadmill exercise. The larger exercising muscle mass is an important determinant of many exercise parameters; for example, greater muscle mass involved in exercise also dictates the relative contribution of stroke volume (SV) and HR in determining cardiac output during exercise. Indeed, some measure of lean leg volume or muscle cross-sectional area is perhaps the single best predictor of $\dot{V}O_{2\max}$. There is some evidence that as children grow into adults, their leg volume increases in greater proportion to their body mass. Because body mass—or better still, lean leg mass—increases considerably during the period of growth and maturation, $\dot{V}O_{2\max}$ rises considerably when expressed in absolute terms (L/min), particularly in postpubertal males (Fig. 7.3A). If $\dot{V}O_{2\max}$ were related to lean body mass, there ought to be no difference between boys and girls in achievable values of $\dot{V}O_{2\max}$, at least not before puberty. On the other hand, $\dot{V}O_{2\max}$ normalized for weight ($mL/kg/min$) remains relatively constant in boys between ages 6 and 18 years, whereas in girls $\dot{V}O_{2\max}$ remains relatively constant between the ages of 6 and 13 years, but levels off or even declines slightly after puberty in girls (Fig. 7.3B).

Figure 7.3. Part A illustrates a composite graph of $\dot{V}O_{2\max}$ in absolute terms versus age in children, whereas part B depicts the relationship with $\dot{V}O_{2\max}$ normalized for body mass. (From Bar-Or O, Rowland TW. *Pediatric Exercise Medicine—From Physiologic Principles to Health Care Application*. Champaign, IL: Human Kinetics, 2004, with permission).

This decline in girls probably represents the effect of increased body fat (or decreased lean body mass) coupled with the recently demonstrated trend in decreasing levels of daily physical activity in adolescent girls. Thus, in adolescence, it is fair to say that boys have a higher $\dot{V}O_{2\max}$ than girls, whether expressed in absolute or relative terms, but apart from this generalization the picture remains unclear. Prior to that age, $\dot{V}O_{2\max}$ of boys and girls differs little although even this conclusion depends on the center, exercise protocol, and methods.

There are two important caveats to any conclusion or statement about $\dot{V}O_{2\max}$ in pediatrics: one pertains to longitudinal versus cross-sectional study data, and the other concerns the method of scaling or normalization of the data (as noted above). Investigators have searched for the best method of indexing $\dot{V}O_2$ and considerable controversy persists as to the best method, if one indeed exists. Based on the dimensionality theory, an exponent of body length was proposed using an exponent from 1.5 to 3.21, and Astrand and Rodahl (11) suggested using length to the 2.9 power. Body weight (mass) expressed simply in kilograms has been criticized as a method for explaining growth-related changes because it led to spurious correlations, misinterpretation of data, and erroneous conclusions. Exponents for body mass or weight ranging from 0.7 to 1.0 have been reported (12,13). This is particularly relevant given our current obesity epidemic. In the final analysis, the most commonly accepted and simplest method of indexing $\dot{V}O_2$ in clinical exercise testing is to use body weight (kilograms), but with recognition of the limitations of this approach. Said limitations become particularly relevant to compilation of normal reference standards that are inevitably derived from large cross-sectional sampling of a pediatric population, usually without regard to stage of physical development and pubertal maturation. Longitudinal studies have clearly shown that there are differences in the change of $\dot{V}O_{2\max}$ over the age span 8 to 16 years. There are different individual trajectories for $\dot{V}O_{2\max}$ during these growth years, which depend not only on age, sex, height, and weight but also on training (14,15). In essence, the so-called normal range is merely a composite of individual single time-point data. Thus, if one studies the same individual repeatedly over his/her growth years, which is probably more meaningful in the clinical arena, one must bear in mind the pitfalls of applying normal population reference standards to an individual patient.

There appear to be minor racial differences in $\dot{V}O_{2\max}$, at least in North American studies. Several small studies have shown lower $\dot{V}O_{2\max}$ in African American children compared with Caucasian children. African American children have slightly smaller lung volumes than Caucasian children of similar standing height, and this alters ventilatory strategy during exercise slightly, but ventilation is not thought to limit exercise in health. One study concluded that slightly lower hemoglobin values and levels of habitual activity in African American children accounted for part of the lower $\dot{V}O_{2\max}$ observed (16).

Considerable attention has focused on the so-called anaerobic threshold as a surrogate measure of maximal aerobic power. Theoretically, it might allow assessment of exercise capacity using a submaximal exercise study, a potential advantage in children who have difficulty achieving a true $\dot{V}O_{2\max}$. The term anaerobic threshold has given way to the term ventilatory threshold (VT) in recent years, in recognition of the fact that this time point during incremental exercise does not reflect the "onset" of anaerobic metabolism as was once hypothesized (17). The ventilatory (anaerobic) threshold (VT or VAT) is defined as $\dot{V}O_2$ at which there is a disproportionate increase in minute ventilation (\dot{V}_E) relative to oxygen uptake. A rise in mixed expired O_2 concentration is observed at this point. There frequently is a disproportionate rise in lactate production at this point as well, hence

Figure 7.4. The relationship of cardiac output to oxygen uptake for normal persons. The various lines represent measurements from different laboratories using a variety of techniques for measuring cardiac output.

the term anaerobic threshold, but an increased lactate is not necessary for the disproportionate rise in \dot{V}_E to occur (18). Breath-by-breath measurement of ventilatory indices and brief incremental workloads are preferable for determining the anaerobic threshold. There are several methods of identifying this point, but the V-slope method is the most common and likely the most reliable in pediatrics (19). This point must also be distinguished from the second inflection or respiratory compensation point. At this juncture during incremental exercise, \dot{V}_E increases out of proportion to $\dot{V}CO_2$, such that $\dot{V}_E/\dot{V}CO_2$ also begins to rise, and end-tidal CO_2 partial pressure begins to fall. This change is attributed to the H^+ -mediated drive to breathe created by blood lactic acid accumulation that has outstripped buffering capacity. Reybrouck et al. (20) reported an inability to detect a VAT in 10% of children. In normal boys, they found a gradual decrease in VAT between ages 8 and 16 years. VAT was lower for girls than for boys. When expressed as a percentage of $\dot{V}O_{2max}$, VAT declined from approximately 65% in 8-year-old boys to approximately 55% in 16-year-old boys. It decreased from 62% in 8-year-old girls to approximately 55% in 16-year-old girls, similar to adult values. Apropos the earlier discussion pertaining to the concept of a “threshold” during an incremental exercise test, more recent studies indeed demonstrated (i) strong correlation between lactate (ventilatory) threshold during incremental cycle exercise and exaggerated reduction in muscle oxygenation measured by NIRS and (ii) muscle deoxygenation trends recorded during short-duration, high-intensity exercise indicate that substantial aerobic metabolism persists during such exercise (21).

CARDIAC RESPONSES TO EXERCISE

The importance of cardiac output and $\dot{Q}O_2$ as a determinant of exercise capacity has already been stated. Cardiac output (\dot{Q}) rises linearly with increasing $\dot{V}O_2$ (Fig. 7.4), the relationship described by

$$\dot{Q} = k\dot{V}O_2 + 4$$

where k averages somewhere between 5 and 7 (22). The intercept, 4, is obviously somewhat dependent on the size of the subject but is a good approximation for children within the

Figure 7.5. Heart rate versus work in children, illustrating sex and size (height) differences. (From Godfrey S. *Exercise Testing in Children*. London, UK: WB Saunders Co. Ltd., 1974, with permission).

“testable” age range (23). These relationships were obtained from steady-state exercise studies, but more recent work done during non-steady-state, progressive tests employing ramp or short-duration (e.g., 2 minute) step increments suggest this linearity may not be maintained. Stringer et al. (24) demonstrated a noticeable leveling or plateau in the $\dot{Q} - \dot{V}O_2$ relationship in four out of five subjects using invasive methods to measure \dot{Q} during ramp exercise to voluntary exhaustion Beck et al. (25) showed that 38% of 72 healthy adults demonstrated nonlinearity in their $\dot{Q} - \dot{V}O_2$ relationship during progressive exercise and that subjects with higher $\dot{V}O_{2max}$ tended to exhibit a leveling off \dot{Q} when plotted versus $\dot{V}O_2$. Rowland (26) recently demonstrated slight nonlinearity in the $\dot{Q} - \dot{V}O_2$ relationship in preadolescent boys during progressive, maximal exercise with 3-minute increments, but the departure was so slight that one could still parsimoniously estimate a linear trajectory. The discrepancy between steady-state and non-steady-state behavior of the $\dot{Q} - \dot{V}O_2$ function is likely the result of different time constants for \dot{Q} versus $\dot{V}O_2$. In other words, if one of these variables reaches steady state more quickly than the other, there will be increasing divergence from the steady-state relationship (5 to 7 L/min per L/min $\dot{V}O_2$), eventually creating a curved function when one is plotted against the other. Since time constants for HR and $\dot{V}O_2$ are faster in children than in adults, this non-linearity may not be so evident in children. However, the dearth of data on kinetics of \dot{Q} in children (and paucity of such data in adults) prevents one from drawing firm conclusions, and underscores deficits in our understanding the dynamics of non-steady-state exercise in children.

Cardiac output is the product of HR \times SV. Stroke volume is dependent on preload, afterload, and myocardial contractility. Clinically useful proxy measures for these could be end-diastolic volume (EDV), blood pressure, and shortening fraction or preferably ejection fraction (EF), respectively. End-systolic volume (ESV) is the difference between EDV and SV, and since $EF = 100(SV/EDV)$, the basic determinants of \dot{Q} are HR, EDV, and EF.

Heart Rate

For normal persons, increased HR during exercise is the major determinant of increased cardiac output. There is a more or less linear relationship between HR and work. The “more or less”

qualification is warranted because some children will show a lesser increment in HR with step changes in work at near-maximal exercise. Indeed, Godfrey et al. (23) have shown that a plot of HR versus logarithm $\dot{V}O_2$ yield a linear plot. It can be seen from Figure 7.5 that, in general, smaller children will have higher HR than larger children at any given work, and girls will have slightly higher HR than boys—particularly after puberty. Maximum heart rate (HR_{max}) that can be achieved is an important determinant of $\dot{V}O_{2max}$. For subjects between 5 and 20 years of age, HR_{max} is about 190 to 205 beats per minute (bpm). The HR_{max} for children younger than 5 years of age probably is similar, but it is difficult to motivate these young children to perform a truly maximal test. For subjects older than 20 years, HR_{max} is equal to $210 - 0.65 \times \text{age}$. The reasons for the decline of HR_{max} with age are unclear but may be related to fibrosis and scarring of the sinoatrial node. Maximum heart rate will vary slightly depending on the exercise protocol used and the type of exercise performed. For example, a slightly higher HR_{max} is obtained for treadmill than for cycle exercise.

Four typical HR patterns during progressive or incremental exercise are illustrated in Figure 7.6. The “normal” graph represents the HR response of a normal subject with an HR_{max} of 200 bpm and $\dot{V}O_{2max}$ of 2.5 L/min. While achieving predicted HR_{max} could be considered indicative of a maximum effort, very fit individuals can continue exercising while HR remains at its maximum value for 1 to 2 minutes. Obviously, this can occur only at the expense of extreme anaerobic energy production. The curve labeled “conditioned” illustrates the HR response if the subject improves his or her physical fitness. With improved fitness, resting HR declines, the so-called training bradycardia. Maximum heart rate does not increase, but it occurs at a higher $\dot{V}O_{2max}$. The curve labeled “deconditioned” illustrates the effect on HR response of deconditioning. Resting HR is higher than control, and HR_{max} occurs at a lower $\dot{V}O_{2max}$. The curve labeled “submaximal” could represent simply inadequate effort, but this curve also is typical of patients with chronotropic insufficiency, that is, low HR_{max} , which occurs in many patients with heart disease with or without prior cardiac surgery.

Stroke Volume

In contrast to the relative ease with which HR is measured, SV measurement has been a daunting challenge because of the invasive nature of methods available in the past. Therefore, our

Figure 7.6. Diagrammatic representation of the relationship between heart rate response to exercise and oxygen consumption. Four different conditions are depicted.

understanding of the behavior of SV during exercise in children has largely been by extrapolation of work done in adults, or based on a limited number of small pediatric studies. Changes in SV during exercise depend to some extent on the position in which exercise is performed. SV approaches its maximum in the supine position, such that when exercise is performed supine there is limited rise in SV. The change in SV that occurs with upright exercise in children is illustrated in Figure 7.7. SV increases primarily early in exercise and increases little thereafter. Thus, the change in cardiac output effected by change in SV occurs early in exercise, and additional changes of cardiac output depend predominantly on the HR.

Parsing the circulatory adaptations to cardiac performance during exercise, one can see that EDV and EF must increase as well in order to explain the rise in SV and fall in ESV. The limits of SV augmentation will be reached when the rapidly increasing HR limits ventricular filling during diastole. Since most ventricular filling occurs in early diastole, left ventricular relaxation and compliance become important variables in the EDV response to exercise. As mentioned in the section above, some children will show a lesser increment in HR with step changes in work at near-maximal exercise. Unless one achieves a plateau for $\dot{V}O_2$, it follows that cardiac output is still rising,

Figure 7.7. Normal range of SV in healthy children plotted against oxygen uptake, with 95% confidence interval. (From Pianosi PT, unpublished data).

which implies that SV must continually increase even near maximal exercise. As simple as this logic appears, demonstrating this has been a challenge, and was the topic of a recent debate in the physiology literature (27). In adults, conventional wisdom states that on average, SV levels off beyond 30% to 40% of $\dot{V}O_2$ max, and most studies (nearly all done in adults) indicate that SV falls at or near maximal exercise except in highly trained individuals in whom it may still rise slightly. Rowland et al. (28) reached similar conclusions in boys. In contrast, Eriksson et al. (29), in one of the few invasive studies of upright cardiac output in children, noted that six of eight subjects achieved their largest SV at maximal exercise. There is a decline in ventricular diastolic compliance with age that is not evident in childhood, but over several decades the ventricles become less compliant and active relaxation becomes impaired. It should therefore come as no surprise that healthy children ought to, in fact, be able to continuously increase SV during progressive exercise, presumably because the younger myocardium has better relaxation kinetics and compliance. Although this supposition remains to be proven, recent work suggests a steady but gradual rise in SV in children during progressive exercise (30).

Another approach to this question is to examine a surrogate measure for SV that can be determined from simple, noninvasive measurements. Rearranging the Fick equation:

$$SV \cdot HR = \frac{\dot{V}O_2}{C_aO_2 - C_vO_2}$$

one obtains:

$$SV \cdot (C_aO_2 - C_vO_2) = \frac{\dot{V}O_2}{HR}$$

The right side of the equation is termed the oxygen pulse, and gives some idea of SV if one assumes a value for arteriovenous O_2 content difference. There is good evidence from adult studies that $C_aO_2 - C_vO_2$ rises linearly with increasing work (24,31). HR and $\dot{V}O_2$ obviously can be measured fairly easily during exercise with modern metabolic carts, and the quotient $\dot{V}O_2/HR$ is known as the oxygen-pulse (mL/beat). While this approach may have some validity in healthy adults, including those with heart failure, there are too many underlying assumptions that render it unwise to extrapolate this approach to pediatric subjects. Moreover, there is a similar dearth of published normal values for oxygen pulse in children (32), an area ripe for future research.

Blood Pressure

During isotonic exercise, systolic blood pressure increases whereas diastolic blood pressure changes little, though, on average, may vary within 10 mm Hg from resting level. Larger children have a higher blood pressure at submaximal and maximal exercise than smaller children (Fig. 7.8). Among similar-sized children, boys have higher peak systolic blood pressure than girls. African American children have a greater blood

Figure 7.8. Nomograms for systolic blood pressure at peak exercise in children according to race and sex. Solid lines represent 50th percentiles, and dashed lines represent (top to bottom) 95th, 75th, 25th, and 5th, percentiles, respectively. (From Alpert BS, Flood NL, Strong WB, et al. Responses to ergometer exercise in a healthy biracial population of children. *J Pediatr* 1982;101:538–545. Copyright Mosby-Year Book, Inc. Reprinted with permission.)

Figure 7.9. Composite Schematic illustration of changes in cardiovascular parameters (systolic and diastolic BP, cardiac output [\dot{Q}], mean arterial pressure and systemic vascular resistance) during exercise in children. Magnitude of each relative change shown gathered and derived from different published sources of normative pediatric exercise data.

pressure response to exercise than white children (33). Mean arterial pressure (MAP) increases during isotonic exercise are due to increased cardiac output and higher systolic pressure, despite a rather marked reduction in total systemic resistance ($SVR = MAP/\dot{Q}$) as shown in Figure 7.9. In contradistinction to this pattern, blood pressure response to isometric exercise is quite different from that during isotonic exercise. With isometric exercise, both systolic and diastolic pressure will increase. Indeed, with power weight lifting, systolic blood pressure may reach 400 mm Hg.

Regulation of Circulation during Exercise

It is important to appreciate the dynamics of this process, that is, the mechanisms leading to the rise in HR, SV, and BP, with exercise as this provides insights into the regulation of circulation. Many physiologic systems involving bulk flow (blood, air) have models in basic physics such as electrical analogues, for example, voltage = current \times resistance. An electrical circuit is characterized by a capacitance or an inductance, and inductance can be in phase or out of phase. Inductance is defined as the property of a circuit to oppose any change in current, and when a circuit has an inductive component, current lags voltage. Capacitance is the property of a circuit to oppose any change in voltage, and current leads voltage in a capacitance circuit. The circulatory equivalents are obviously pressure (voltage) and flow (current). Conceptualizing the cardiovascular system as a capacitance circuit is a useful paradigm. During exercise, the heart must pump more per beat, into a systemic circulation under higher pressure, and in turn receives more blood return from the exercising limbs via the muscle pump phenomenon. Blood pressure rises in response to this increased flow through the circuit but there are concomitant changes in distribution of this increased cardiac output to other vascular beds geared to maintain central blood volume and perfusion through exercising muscles. In order for this process to accommodate the requirements of dynamic exercise of increasing intensity, total peripheral vascular resistance must fall significantly. Whether pressure leads flow or lags flow in the cardiovascular system is a subject of intense interest to physiologists because it cuts to the heart of control of circulation during exercise.

An interesting model to study this paradigm is postural orthostatic tachycardia syndrome (POTS) or adolescent autonomic dysfunction as it is called in pediatric circles (35). POTS comprises a constellation of symptoms and affected individuals represent a heterogeneous population who share certain abnormalities in the regulation of circulation. One hypothesis argues that after some initiating event, deconditioning plays a major pathophysiologic role (35). Functionally, a conceptual model with three groups: “low-flow,” “normal-flow,” and “high-flow” patients with POTS has been developed (36), and our experience at Mayo clinic lends some early support to this concept (37). Patients with low-flow POTS demonstrate low blood flow and high arterial resistance, attributed to abnormalities in local blood-flow regulation and mild hypovolemia. In contrast, normal-flow POTS patients exhibit normal flow and systemic resistance in supine position, and manifest increased peripheral resistance after standing. This is thought to result from splanchnic pooling and distributive hypovolemia. High-flow POTS patients display low arterial resistance and high blood flow with increased cardiac output, possibly attributable to a hyperadrenergic state or long-tract autonomic neuropathy. One of the most consistent findings in patients with POTS is the presence of relative low blood volume, which can result in decreased venous return (preload). In response to this, normal physiologic responses generate tachycardia, to provide a compensatory increase in cardiac output. The symptoms and pathology of POTS are consistent with relative central hypovolemia, in which systemic volume may be normal but a state of intrathoracic hypovolemia exists (38). Many of these signs and symptoms can result from prolonged bed rest or following spaceflight—conditions that cause deconditioning. A recent study found that many of these pathophysiologic changes improved after a period of aerobic training (39).

The electrical analogue described above may prove useful in understanding the pathophysiology of this syndrome, that is, whether the cardiovascular system behaves as a capacitance or inductance circuit. Examination of Figure 7.9 gives one some idea of how alterations in one parameter, for example, hyperdynamic circulation with changes in cardiac output exceeding those predicted from the normal $\dot{Q} - \dot{V}O_2$ relationship, might compensate for low MAP in a patient with POTS whose systolic pressure barely nudges above resting levels. In this scenario, the circulatory system acts like a capacitance circuit in as much as current (cardiac output) leads voltage (pressure). In contrast, the circulatory system of low- and normal-flow POTS patients appears to behave more like an inductance circuit, where current (flow) lags voltage (pressure). Nonessential (from the point of view of meeting exercise needs) circulatory beds such as the gut act as large inductance coils, sapping the current (blood flow) during upright exercise. Such modeling may answer the “how” but not necessarily the “why” POTS patients respond to exercise as they do.

Fitness

Improved fitness occurs with repetitive exercise—the “training effect”. From a strict physiologic standpoint, improved fitness implies an increase in $\dot{V}O_{2\max}$. Many studies in adults have demonstrated increases in $\dot{V}O_{2\max}$ as a result of a conditioning or fitness program. In children, it has been more difficult to demonstrate this effect, probably because “normal” children simply are more fit than “normal” adults to begin with; hence, it is more difficult to demonstrate a change in fitness in normal children. However, a recent longitudinal study in athletic children demonstrated that the type of physical activity did indeed affect the change in $\dot{V}O_{2\max}$ during childhood (14). The importance of this observation may become more relevant in

this era of increasing childhood obesity and decreasing fitness levels in today's youth.

As demonstrated in Figure 7.6, resting HR decreases with improved fitness, and HR_{max} occurs at a higher $\dot{V}O_{2max}$. It is apparent from this figure that submaximal HR is lower at any $\dot{V}O_2$ in the fit person compared with that in the unfit person. These adjustments of HR occur because of the increase in SV that occurs with conditioning. Also, changes in the parasympathetic and sympathetic regulation of HR probably play an important role, with a relatively greater parasympathetic (vagal) influence on HR in the fit person. Changes in fitness or conditioning are not limited to changes in function of the cardiovascular system. The ventilatory changes listed are not the result of changes in resting lung function but are due to improved oxygen delivery and utilization, which thereby reduce ventilatory requirements in heavy exercise. Important changes also occur in subcellular changes in muscle and indeed, it is these changes that can contribute more to improved fitness with training. These are listed in the Table 7.1. Fitness can be improved with regular episodes of sustained exercise. Conversely, deconditioning occurs if regular exercise is not done. Because children with heart disease may be sedentary, some component of reduced aerobic capacity in these patients may result from deconditioning.

VENTILATORY RESPONSE TO EXERCISE

Ventilation increases because of increases in both tidal volume (V_T) and breathing frequency (Fig. 7.10). Similar to HR, submaximal respiratory rates (RR) are higher in younger children at any given work rate. As children grow, the respiratory rate at peak exercise declines, particularly above age 12 to 13 years. Younger children will typically achieve a peak RR of 60 breaths per minute, whereas older children will generally achieve RR of 50 breaths per minute in early adolescence to 40 breaths per minute in late adolescence, at maximal exercise. In part this is due to the obligate dead space ventilation, but is largely due to the relatively larger increase in

vital capacity with growth allowing more room for V_T recruitment. Tidal volume, in general, does not level off with increasing exercise intensity, though some individuals with marked hyperventilation at maximal exercise actually will sacrifice V_T for higher breathing frequency. V_T increases commensurate

Figure 7.10. Relationships between ventilatory variables at maximum exercise in healthy children of varying age and height. (From Godfrey S. *Exercise Testing in Children*. London, UK: WB Saunders Co. Ltd., 1974, with permission).

with growth of vital capacity during childhood and adolescence but at maximal exercise V_T reaches a level at least 40% and as much as 60% of vital capacity regardless of age. This is accomplished by encroaching somewhat on the expiratory reserve volume but predominantly by tapping into the larger inspiratory reserve volume. This strategy has important implications in determining the cause(s) of exertional dyspnea.

The relationship between ventilation and work is linear until (VAT) is attained. Ventilation most closely tracks carbon dioxide output ($\dot{V}CO_2$) during exercise and the ventilatory response to progressive exercise can be characterized as $\Delta\dot{V}_E/\Delta\dot{V}CO_2$. This slope falls slightly with age and growth during childhood (40). The ventilatory equivalent for CO_2 ($\dot{V}_E/\dot{V}CO_2$) dictates the volume of air breathed relative to the volume of CO_2 produced. By analogy, the ventilatory equivalent for O_2 ($\dot{V}_E/\dot{V}O_2$) describes the volume of air breathed relative to the volume of O_2 consumed. These parameters traditionally have been measured during steady-state exercise. $\dot{V}_E/\dot{V}O_2$ declines early in exercise as a result of better ventilation and blood flow matching in the lungs as pulmonary blood flow increases and flow redistributes to the apices of the lungs. The point during exercise when $\dot{V}_E/\dot{V}O_2$ begins to increase describes the VAT. The gas exchange ratio (R value) is the quotient $\dot{V}CO_2/\dot{V}O_2$. Normally it is measured during steady-state conditions and reflects the mixture of energy sources consumed at rest or exercise; as such, it becomes a measure of the cellular respiratory quotient (RQ). Children consuming a ketogenic (high fat) diet will have an R near 0.7, but the typical resting value is usually

approximately 0.8, again reflecting the carbohydrate and fat mix of a child's average daily food consumption. During incremental exercise both $\dot{V}O_2$ and $\dot{V}CO_2$ creep upward with increasing work, but $\dot{V}CO_2$ does so at a slightly faster rate than $\dot{V}O_2$. This gradual rise in $\dot{V}CO_2$ relative to $\dot{V}O_2$ means that R value approaches unity as power rises. Beyond this point $\dot{V}CO_2$ then rises disproportionately to $\dot{V}O_2$ as exercise continues above the VAT. Exercise hyperpnea that was linearly related to $\dot{V}CO_2$ maintains its tight coupling for a variable period even after the point when $\dot{V}_E/\dot{V}O_2$ begins to increase (VAT) (Fig. 7.11). In other words, at VAT the slope of $\dot{V}_E/\dot{V}O_2$ increases, but the slope of $\dot{V}_E/\dot{V}CO_2$ does not, until increasing work results in acidosis. At this point \dot{V}_E increases disproportionately to $\dot{V}CO_2$, resulting in a rise in $\dot{V}_E/\dot{V}CO_2$. As power inches further toward maximum and \dot{V}_E outpaces metabolic requirement ($\dot{V}CO_2$), an inflection point in $\dot{V}_E/\dot{V}CO_2$ occurs. This constitutes the respiratory compensation point, and is characterized by hyperventilation with reduction of arterial PCO_2 , generally reaching the low thirties (mm Hg)—lower in younger children compared with adolescents (41).

When exercise ceases at the point of voluntary exhaustion, \dot{V}_E is typically 60% to 70% of maximum voluntary ventilation (MVV), leaving a "ventilatory reserve" of roughly 30% to 40%. Persons with pulmonary disease who encroach on this breathing reserve achieve maximal \dot{V}_E exceeding 70%, and sometimes 100%, of MVV. How is this possible? Caution must be used in assessing the relationship between \dot{V}_E during exercise and MVV measured at rest because obtaining a

Figure 7.11. Changes in ventilatory indices, serum lactate, bicarbonate, and pH with increasing work. The vertical lines represent the onset of the VAT (left line) and the threshold for decompensated acidosis (right line). (From Wasserman K, Hansen J, Sue D, et al. *Principles of Exercise Testing and Interpretation*. Philadelphia, PA: Lea & Febiger, 1987.)

true measure of rest MVV depends greatly on subject effort. If the subject does not make a good effort, a factitiously low MVV will be recorded, and the relationship with \dot{V}_E during exercise will be misleading. A true MVV should approximate 1-second forced expiratory volume (FEV_1) \times 35 or 40. This long-held index has other limitations, principally because the operating lung volume of the resting MVV maneuver differs from the actual operating lung volume during exercise. A better way to determine whether exercise is limited by ventilation is by measurement of tidal flow-volume loops during exercise (42), which may have the added advantage of detecting vocal cord dysfunction, an increasingly recognized cause of exertional dyspnea. This is depicted in Figure 7.12, and has recently been studied in normal children (43,44). In a manner analogous to SV, V_T normally increases both by breathing at a lower end-expiratory lung volume (equivalent to LV-ESV) and attaining a higher end-inspiratory lung volume (higher LV-EDV). A small contribution comes from the expiratory reserve volume whereas the lion's share of V_T recruitment occurs by tapping into inspiratory reserve volume.

Diffusion limitation is seldom, if ever, a problem during routine clinical exercise testing. It may become a factor at extremes of exercise in high-performance athletes, as transit

time through the pulmonary capillaries may be short enough (very high levels of cardiac output) to preclude equilibration of alveolar and end-capillary PO_2 . Such an individual might even experience arterial desaturation if she/he had an intrinsically low hypoxic ventilatory response (45). Normal, healthy children should not exhibit desaturation even at maximal exercise but this area has not been studied specifically in children with the exception of one report (46). These authors concluded (with a few caveats) that exertional desaturation can occur in 25% to 33% of physically active children with normal (vs. supranormal) $\dot{V}O_{2\max}$ values. Given the technical difficulties in precise determination of oxygen saturation by pulse oximetry during exercise, healthy skepticism seems warranted.

METHODOLOGY OF EXERCISE TESTING

Types of Exercise and Ergometers

Treadmill and stationary cycles are the two most frequently used ergometers for clinical exercise testing. Neither is inherently superior to the other; each has advantages and disadvantages. Most people can walk reasonably efficiently, but not everyone can cycle efficiently. Children younger than 4 or 5 years of age may have more difficulty using a cycle ergometer than a treadmill. On the other hand, a treadmill may be more dangerous than a cycle because the subject can fall from the treadmill. Also, it is more difficult to hear the Korotkoff sounds when the subject is running or jogging on a treadmill than when he or she is cycling. If the subject is connected to numerous monitoring devices, cycling may be preferable because it involves less movement of the trunk and extremities. In general, it is easier to calibrate a treadmill than a cycle ergometer.

The two general types of cycle ergometers are the mechanically braked and electronically braked. With a mechanically braked cycle ergometer, power changes with changes of pedaling frequency. With an electronically braked cycle ergometer, moderate changes in pedaling frequency do not affect power substantially. Thus, for untrained subjects, who may have difficulty maintaining a steady pedaling frequency, electronically braked cycles are preferable. Other, less frequently used ergometers are handgrip ergometers and arm crank ergometers. The arm-crank ergometer is useful for subjects who are unable to walk or cycle or for whom physiologic measurement of upper extremity function is of interest.

Exercise Protocols

There is no "best" exercise protocol. Examiners should select or create a protocol that best allows measurement of the responses to exercise that are of particular interest. One may use a protocol that has been standardized in another laboratory. Ideally, protocols should be standardized and data obtained for a "normal" population in the laboratory in which the clinical exercise testing is done. Power increments should not be excessive; otherwise, some subjects may stop exercise before a maximum cardiorespiratory effort has been achieved. Power increments too small result in unnecessarily long tests, which can be a challenge in a child with short attention span. In general, exercise protocols should be designed such that the duration of the exercise test is 8 to 12 minutes, since children become disinterested with longer tests and effort wanes. The Three well-standardized protocols for treadmill exercise are detailed in Tables 7.2 to 7.4.

The Bruce protocol is arguably the most commonly employed in children. For children and subjects incapable of much exercise, a modified Bruce protocol can be used in

Figure 7.12. New method to assess ventilatory limitation to exercise. Exercise tidal flow volume loops (ext FVL) are superimposed within the maximal flow volume loop (MFVL) determined at rest, and any overlap is considered evidence of flow limitation (V_{FL}). EELV and EILV are end-expiratory and end-inspiratory lung volumes, respectively; while IRV and ERV are inspiratory and expiratory reserve volumes, respectively. Lung volume is plotted on the abscissa with total lung capacity (TLC) at the origin, while flow is on the ordinate, with expiration above the volume axis and inspiration below. (From Johnson BD, Weisman IM, Zeballos RJ, et al. Emerging concepts in the evaluation of ventilatory limitation during exercise: the exercise tidal flow-volume loop. *Chest* 1999;116:488–503. which the initial two steps use a belt speed of 1.7 mph and an incline of 0% and 5%, respectively (47). For cycle testing, the James (48) protocol is useful because the 3-minute duration of each work increment make it very likely that steady state is achieved at each load. On the other hand, the large jump in power (50 W for child with body surface area (BSA) more than 1.2 m²) results in some smaller children being unable to persevere despite not having achieved their true maximum work capacity or aerobic power. Ramp protocols may come to be used more and more frequently as investigators acquire the equipment to perform this type of study. The ramp protocol uses a constantly increasing workload where the increment, regardless of magnitude, occurs as a gradual and continuous procedure instead of a step each minute. Obviously, this protocol is not suited for assessing physiologic functions that require steady-state exercise. A good compromise is the standard

incremental cycle ergometer protocol with increments in work every 1 or 2 minutes, with the size of the increments tailored to the anticipated maximum capacity for each subject, such that test duration is 8 to 12 minutes. This will also provide enough data points to plot and analyze physiologic parameters with confidence.

TECHNIQUES OF SPECIFIC MEASUREMENTS

Heart Rate and Electrocardiogram

HR, one of the basic indices of cardiac response to exercise, is measured from the electrocardiogram (ECG), which can be done manually by averaging several R-R intervals. Alternatively, the ECG signal can be processed through a tachometer, and a direct recording of HR based on one or more R-R intervals can be obtained. At least three leads of the standard surface ECG should be displayed or recorded continuously during, and for 5 to 10 minutes after completion of, an exercise test. The examiner should have the option of viewing various combinations of leads so that inferior, right, and left precordial cardiac events can be assessed. A complete ECG should be recorded at rest, at least once during each workload, and for several intervals after exercise. Ideally, the ECG should have several recording speeds. Obtaining an ECG at a speed of 50 mm/sec facilitates assessment of ST segment changes. Continuous recording of the ECG at 5 mm per second paper speed facilitates detection of arrhythmias.

Appropriate application of the ECG electrodes and leads and electric shielding of the cable connecting the leads to the electrocardiograph are important for obtaining high-quality, artifact-free recordings. The subject's skin should be cleansed with alcohol and abraded lightly to reduce electric skin resistance. Most commercially available electrodes are prepackaged with electrode paste; occasionally, however, no paste is present, and these electrodes must be discarded or paste applied before using them. Note that pregelled electrodes have a limited shelf life due to chemical changes in the conducting paste,

and should be discarded if they are old and signal quality visibly deteriorates. The wire leads connecting the individual electrodes to the ECG cable should be secured to the subject's torso to minimize artifact from movement of these electrodes during exercise. This can be accomplished by loosely wrapping the torso with an elastic bandage or by using a commercially available knit shirt. The presence of artifact on the ECG usually indicates a loose lead-electrode interface, a poorly applied electrode, or inadequate electrode paste.

Blood Pressure

Blood pressure is an essential measurement in evaluating the cardiovascular response to exercise. Blood pressure can be measured directly with an indwelling arterial catheter or, more commonly, indirectly with a cuff, a sphygmomanometer, and a stethoscope. Numerous commercially available electronic units are available to measure blood pressure indirectly during exercise. The accuracy and precision of these "black boxes," however, must be a concern. Devices designed to inflate and deflate the cuff automatically coupled to a microphone that can be secured over the brachial artery are useful. It is critical to use an appropriate-size cuff. The bladder of the cuff should encircle the arm completely, and the width of the cuff should be at least two-thirds the length of the upper arm. An oversized cuff should be available to measure leg blood pressure when indicated. It should be remembered that accurate measurement of diastolic blood pressure during exercise is extremely difficult, particularly during treadmill exercise, because the pounding feet and the noise of the treadmill make it difficult to hear Korotkoff sounds. Direct (intra-arterial) blood pressure measurement allows nearly instantaneous beat-to-beat monitoring of blood pressure with a high level of precision. Because of peripheral amplification, however, measurement of blood pressure in the distal vascular system (radial or brachial artery) overestimates central aortic blood pressure (Fig. 7.13). In addition, this technique is invasive and potentially painful, which limits its usefulness in children.

Figure 7.13. The relationship between systolic blood pressure measured using an indwelling radial artery cannula and arm blood pressure measured with a sphygmomanometer. Note that the blood pressures measured using a radial artery catheter are greater than those using a sphygmomanometer. (Reproduced from Rassmussen P, Staats B, Driscoll D, et al. Direct and indirect blood pressure during exercise. *Chest* 1985;87:743–748, with permission.)

Cardiac Output and Stroke Volume

The two techniques used most frequently to measure cardiac output (\dot{Q}) relatively noninvasively and without the need for radioactive material are the CO_2 and the acetylene-helium ($\text{C}_2\text{H}_2\text{-He}$) rebreathing techniques, although third, similar technique—nitrous oxide (N_2O)—has recently been reevaluated. The renewed interest in inert gas (N_2O and acetylene) has occurred with the advent of newer, less finicky, gas analyzers.

The CO_2 rebreathing technique (Fig. 7.14) is based on the Fick principle for CO_2 :

$$\dot{Q} = \frac{\dot{V}\text{CO}_2}{C_v\text{CO}_2 - C_a\text{CO}_2}$$

where $\dot{V}\text{CO}_2$ is the volume of carbon dioxide produced, $C_v\text{CO}_2$ is mixed venous blood CO_2 content, and $C_a\text{CO}_2$ is the systemic arterial blood CO_2 content. $\dot{V}\text{CO}_2$ is measured directly, arterial CO_2 content is calculated from the measurement of systemic arterial blood PCO_2 , and mixed venous CO_2 content is calculated from the measurement of end-tidal (alveolar) PCO_2 , assuming equilibrium with mixed venous PCO_2 and alveolar PCO_2 during the rebreathing maneuver. The latter maneuver can be done by the classical equilibrium or the exponential technique (49,50). The latter is simpler during incremental exercise and better tolerated because it utilizes lower CO_2 concentration in the rebreathing mixture. Inhaled CO_2 can create an unpleasant taste and transient headache in high concentrations. The need to measure systemic arterial PCO_2 is a disadvantage of this technique because it is invasive. Systemic arterial PCO_2 can be estimated from end-tidal PCO_2 , or by assuming a normal anatomic dead space in a subject with normal pulmonary function and solving for PaCO_2 using the Bohr equation, since all parameters in this equation are directly measured except for PaCO_2 . Note that one must account for instrument dead space (mouthpiece, face mask). Ultimately however, such approximations introduce additional potential error into the technique. Furthermore the concentration of CO_2 in the rebreathing mixture as well as the volume of the rebreathing mixture must be adjusted to the patient's size and exercise intensity. The future of this method is uncertain because of two recently described methodologic issues: the accuracy of measuring PCO_2 in a high O_2 mixture (51) and the solution to the equation relating CO_2 partial pressures to contents (52). The former problem, known as the collision-broadening effect, effectively limits the CO_2 rebreathing technique to laboratories employing a mass spectrometer to measure exhaled gas concentrations, while the latter underscores the need to know (rather than assume) blood pH and PCO_2 . Until these issues are clarified, healthy critical evaluation of papers using the indirect Fick (CO_2) technique would seem justified.

The $\text{C}_2\text{H}_2\text{-He}$ rebreathing technique to measure cardiac output is based on the principle that acetylene diffuses from the alveolus to the pulmonary capillary (53). The concentration of the acetylene in the rebreathing system declines relative to the volume of effective pulmonary blood flow (Fig. 7.15). This technique actually measures effective pulmonary blood flow rather than systemic blood flow, but in the absence of significant right-to-left or left-to-right intracardiac or intrapulmonary shunt, it is a reliable approximation of cardiac output. The other caveat is that the technique is heavily dependent on even distribution of the inspired gas and will thus be less accurate in patients with lung disease characterized by mismatching of ventilation and perfusion. It is necessary to include a gas that does not diffuse out of the alveolus (e.g., helium) to determine the volume of the entire

Figure 7.14. Diagrammatic representation of the CO_2 rebreathing method of assessing cardiac output. See text for determination of $PaCO_2$.

respiratory system and rebreath apparatus. This technique is completely noninvasive and tolerated well by children. Technically, it is simpler to perform the C_2H_2 -He than the CO_2 rebreath maneuver because the concentration of acetylene, helium, oxygen, and nitrogen used as the rebreath mixture is constant, only the volume of the mixture needs to be altered, depending on the subject's tidal volume. Subjects find the C_2H_2 -He rebreathing technique more comfortable, with less feeling of dyspnea during the procedure than with CO_2 rebreathing. One pediatric study compared C_2H_2 -He versus a somewhat modified CO_2 rebreath maneuvers, and found that only half the CO_2 rebreath maneuvers provided data that could be analyzed (54).

N_2O is highly soluble in blood and rebreathing N_2O was first described as another inert gas technique to measure cardiac output nearly 50 years ago, but has recently undergone reexamination. Like C_2H_2 -He rebreathing, N_2O rebreathing measures effective pulmonary blood flow, and suffers from the same limitations as acetylene method. An insoluble tracer gas is required, and recent studies used SF_6 for this purpose since it is highly insoluble and achieves equilibrium within the bag-lung rebreathing system. When this method was in its infancy, two studies in children (using helium or argon tracers) were published, one of which found the method compared very well with CO_2 rebreathing measurements of cardiac output (55). More recent studies in adults with (56) and without heart

Figure 7.15. Diagram of the acetylene-helium rebreathing technique for measuring effective pulmonary blood flow. Note that with rebreathing there is a constant decay in the concentration of acetylene in the rebreathing system. This occurs because acetylene passes across the alveolar membrane and is taken up by the pulmonary blood flow.

failure have compared N₂O rebreathing with (57) invasive and (58) noninvasive (CO₂) methods of measuring cardiac output. The study by Jarvis et al. (57) was very comprehensive and compared direct Fick, thermodilution, N₂O and C₂H₂ rebreathing methods (plus a 1-step CO₂ rebreathing technique). There are many ways to compare results of different methods of measurement. One is to report bias, that is, how closely one method approximates the gold standard, and precision, that is, how reproducible is the method, or alternatively, what is the variance of repeated trials. These authors concluded that inert gas methods were precise, but tended to underestimate the results obtained by the gold standard method(s) during exercise.

No similar study has been reported in children, nor is one likely. The fact is that these inert gas methods offer promise for using the lungs to measure cardiac output noninvasively in children. Whereas the CO₂ nontechnique can give accurate results in children with lung disease characterized by significant ventilation-perfusion mismatch, provided one *measures* rather than estimates PaCO₂, the same *cannot* be said for inert gas methods. They are predicated on adequate mixing of inspired gas, such that gas contents in the bag mix quickly with alveolar gas. Only once that occurs can these methods accurately measure pulmonary blood flow, which equals cardiac output for all intents and purposes.

The past decade has witnessed several publications on echocardiographic measurement of cardiac output during exercise. With this method, SV is estimated by standard Doppler echocardiographic techniques (59). The cross-sectional area of the ascending aorta is first calculated at rest with subjects in the sitting position from the maximal diameter of the aorta measured by two-dimensional echocardiography (long-axis view) at the sinotubular junction (inner edge to inner edge) assuming the aorta to be circular. Velocity of ascending aorta blood flow is determined with a continuous-wave transducer positioned in the suprasternal notch. The velocity-time integral (VTI) for each beat is calculated off-line by tracing the velocity curve contour over time. The termination of each contour was marked by aortic valve closure. Five to eight curves with the highest values and most distinct spectral envelopes should be averaged for each workload. SV is estimated as the product of the mean VTI and the cross-sectional area of the ascending aorta. The method is reasonably accurate, provided enough beats are averaged to compute stroke volume, since SV is affected by phase of breathing (60), and one risks overestimation of SV and hence cardiac output if one chooses the “best-looking” VTI. The technique also is critically dependent on accurate measurement of aortic valve area. Moreover, obtaining a satisfactory window at the suprasternal notch during heavy exercise can be a challenge both to the person holding the transducer and to the hyperpneic subject. Thus, echocardiographic measurement of cardiac output is very operator dependent, but despite these limitations the method is a choice among the noninvasive options. It has been extensively used by Rowland and coworkers (28,61,62) to study cardiac responses to exercise during the growth period of childhood.

Before concluding this section, one should be aware of the potential for impedance cardiography as a useful clinical and research tool in the pediatric exercise laboratory. It has never gained widespread acceptance because of uncertainty over its theoretical foundations, and because of equivocal findings of previous reports comparing this method with more accepted methods of measuring cardiac output. Recent work may change this thinking (30, 63–67), so a brief description is worthwhile. The theory behind the method models the thorax as a cylinder or truncated cone whose electrical impedance changes in proportion to the electrical conductivity of the blood within, simultaneously with mechanical systole. A tiny, biologically inactive AC current is discharged by one set of electrodes, while another set measures the impedance of the

thoracic contents to this current. SV is computed from thoracic impedance measurements using one of a number of published equations, which contain all or some the following terms:

$$SV = r \cdot (L^2/Z_0^2) \cdot VET \cdot (dZ/dt_{\min})$$

where r is the blood resistivity, a function of packed cell volume; L is the distance between electrodes; Z_0 is the baseline thoracic impedance; VET is the ventricular ejection time; and dZ/dt_{\min} is the maximum rate of fall in impedance. Most devices compute ventricular ejection time from the ECG tracing, though one (30) uses a microphone on the chest to detect the second heart sound. This unique impedance cardiograph required measurement of Z_0 and interelectrode distance (30), whereas others did not (63–67). The most recent iteration of this technology measures the relative phase shift ($\Delta\Phi$) of a radiofrequency signal passing through the thorax (instead of amplitude changes in impedance to an AC microcurrent) between paired electrodes during aortic ejection, which are tightly correlated to blood flow rate (65). This parameter allegedly has a higher signal to noise ratio and simplified the SV equation to:

$$SV = C \cdot VET \cdot (d\Phi/dt_{\max})$$

where C was termed a constant of proportionality, and $d\Phi/dt_{\max}$ is the rate of change in relative phase shift of the impedance signal. Despite claims, it significantly underestimated (bias) cardiac output during exercise in healthy adults compared with an inert gas rebreathing method, and the authors commented that subjects were required to maintain a relatively stable upper body position to reduce signal artifact (66). The precision of impedance cardiography was very good in children, with realistic results reported, though since no comparator measure was employed, one cannot comment on its bias (67). Future studies will determine its role, but it offers a simple, unobtrusive method for measuring cardiac output during exercise in children that yields results comparable to other methods.

Ventilation Measurements

The following indices of ventilation are measured: respiratory rate (RR), tidal volume (V_T), minute ventilation (\dot{V}_E or \dot{V}_I , depending on whether one measures inspired or expired ventilation), oxygen uptake ($\dot{V}O_2$), carbon dioxide production ($\dot{V}CO_2$), end-tidal CO₂, O₂, and mixed-expired CO₂ and O₂. From these measurements, the ventilatory equivalents for oxygen ($\dot{V}_E/\dot{V}O_2$) and CO₂ ($\dot{V}_E/\dot{V}CO_2$) and gas exchange ratio (RER) can be measured. Noninvasive (ear or finger oximetry) measurement of blood oxygen saturation is useful to document the presence or absence, and degree, of hypoxemia. There is very good correlation between blood oxygen saturation measured by pulse oximetry and that measured by direct blood gas analysis at least for oxygen saturations above 75%.

Several technical advances have been made in the measurement of ventilation and gas exchange during exercise, particularly with gas analyzers. This technology has improved in as much as large, cantankerous, mass spectrometers have also been replaced by smaller and more user-friendly gas analyzers permitting determination of concentrations of several gases at one time. Because of smaller size, newer portable metabolic carts containing all the essential tools are now readily available. Some of the old standards such as fuel cell or zirconium oxide O₂ analyzers and infrared CO₂ analyzers remain the workhorses of many such systems, though infrared CO₂

analysis may no longer be considered accurate if employed to analyze CO_2 concentration in high O_2 mixtures. In addition, hardware and software are available to measure indices of ventilation in a breath-by-breath fashion. There are several essential requirements of an ideal system: low sampling volume, rapid sampling rate with ultrafast response times. Software algorithms must account for these delays in computing breath-by-breath $\dot{V}\text{O}_2$ and $\dot{V}\text{CO}_2$, since the actual concentration of the gas at any instant must be matched with the exhaled volume at that same time point, in order to calculate the concentration–time integral.

It no longer is necessary to use timed gas collection into cumbersome Douglas bags and Tissot spirometers. Some commercially available systems still employ a mixing chamber, much smaller than devices used for timed collections, from which mixed expired gases (O_2 and CO_2) are sampled in real time. This requires not only that gas in the chamber is well mixed before expulsion, but also that these concentrations must then be matched with minute volume measured at approximately the same time. By and large, these methods have given way to accurate and reliable respiratory mass flow sensors, Pitot tubes, pneumotachographs, and turbine flowmeters. Measurement of ventilatory indices requires the use of a mouthpiece and a nose clip or a tightly fitting mask, and the latter can be oronasal or partition oral and nasal flow. Most children will tolerate a mouthpiece and nose clip. It is important to have different-sized mouthpieces and three-way respiratory valves available so that the dead space of the system can be minimized for small children. Valve or mask dead spaces volumes typically should be approximately 50 to 70 mL. It is equally important that such exercise systems recognize and subtract valve or mask dead space volume from the total \dot{V}_E before calculating $\dot{V}_E/\dot{V}\text{O}_2$ and $\dot{V}_E/\dot{V}\text{CO}_2$ ratios or slopes. Failure to do so, particularly in children, can result in large error given the smaller tidal volumes of younger children.

Echocardiography: Basic Principles and Imaging

Thomas R. Kimball ■ Erik C. Michelfelder

Although utilization of imaging modalities other than echocardiography (e.g., computed tomography and magnetic resonance imaging) has increased in the evaluation of congenital heart disease (1,2), echocardiography remains the principal diagnostic modality in the field of pediatric cardiology (3). The echocardiography laboratory is often the patient's last "diagnostic stop" before surgical or catheter intervention, which necessitates the most complete anatomic and physiologic description of the cardiovascular system possible and requires unprecedented detail in the echocardiographic evaluation. In addition, pediatric echocardiographers find themselves with two important challenges today: (a) to define, with the help of other imaging specialists, the roles of not only echocardiography but other emerging imaging technologies in the evaluation of complex anatomy in children and adults with congenital heart disease (4) and (b) to oversee the expanding utilization of echocardiography among not only our cardiology colleagues but also other noncardiology health care providers—utilization precipitated in part by poorer auscultatory skills of personnel and increased miniaturization and decreased cost of cardiac ultrasound technology (5,6).

HISTORY

In 1877, Pierre Curie, then only 18 years old, and his older brother, Jacques, found the basis for the field that would later be known as ultrasound by discovering the piezoelectric effect in which mechanical distortion of crystals produces an electric potential and vice versa. Although this was a landmark discovery, it was not until many years later, in fact not until after the 1912 sinking of the Titanic (which catalyzed efforts to create systems aiding ships in earlier detection of icebergs), that the field of ultrasound began to develop (7). Eventually, in World War II, ultrasound waves formed the basis of Sound Navigation and Ranging (SONAR) (8).

The successful use of ultrasound as a diagnostic medical technique was simultaneously pioneered in the 1940s and 1950s by four groups: (a) the Massachusetts Institute of Technology (MIT; Bolt, Ballantine, Ludwig, and Heuter), (b) the University of Illinois (Fry, Fry, and Kelly), (c) the University of Colorado (Howry and Holmes), and (d) the University of Minnesota (Wild and Reid). The MIT group developed A (amplitude)-mode ultrasound, a method of displaying the intensity of reflected waves as spikes of various heights on an oscilloscope. The Illinois group is renowned for using ultrasound to detect breast cancer. The Colorado group developed B (brightness)-mode imaging, a method of displaying the intensity of the reflected ultrasound waves as dots of various brightness along a single scan line, the progenitor to two-dimensional (2-D) ultrasound. They expanded this concept by creating the B-29 gun turret water-bath scanner in which both patient and transducer were immersed. The Minnesota group

perfected pulsed ultrasound techniques that permit a single transducer to act as both a transmitter and a receiver in real time and, by incorporating a water interface in the transducer head, created the first hand-held scanner, thus eliminating the need for patient immersion (7,8).

Applying ultrasound for cardiac diagnosis was first performed at the University of Lund, Sweden (Edler and Hertz) in 1953. A B-mode detector with continuous moving film to obtain real-time images of the heart in waveform provided the first M(motion)-mode echocardiogram (7,8). Twenty years later, M-mode echocardiography was applied to congenital heart disease by Goldberg, Allen, Sahn, Meyer and others (9,10). In the late 1970s and early 1980s, the application of 2-D echocardiography to congenital heart disease allowing complete, accurate, and detailed diagnoses was successfully completed by pioneers such as Sahn, Snider, Silverman, Williams, Stevenson, and others (11–20). Each stressed a thoughtful, considered approach that coupled the evolving field of echocardiography to the established fields of cardiac morphology, pathology, and embryology, eventually forging the way for children, infants, and neonates to receive medical and surgical treatment after an assessment that was completely noninvasive. In the 1990s and early 2000s, ultrasound technology became increasingly miniaturized so that echocardiography began to enjoy broader use including as a bedside adjunct to the physical examination in more unique settings such as the emergency room and the intensive care unit. Such applications have created special challenges for the pediatric echocardiography community which must respond to the training and quality assurance issues associated with a wider user base without being exclusionary. With other imaging modalities such as cardiac MRI becoming more established, echocardiographers will need to work with other imaging specialists to define the role of each of these cardiac imaging tools in the diagnostic workup in all the disease states and patient population which we manage.

PHYSICS OF TWO-DIMENSIONAL ECHOCARDIOGRAPHY

The piezoelectric effect occurs when an electric potential applied to a crystal results in mechanical distortion because of alignment of the crystal's molecular dipoles. This, in turn, causes the crystal to resonate producing ultrasonic waves. A sound wave requires a deformable medium for its propagation because it is mechanical in nature, consisting of a series of compressions and expansions (rarefaction) of the molecules in the medium. The velocity of sound depends on the type of tissue through which it is traveling (1,540 m/s in soft tissue, 330 m/s in air). The wave has characteristics that define its existence (Fig. 8.1).

Figure 8.1. The anatomy of a wave. Sound travels with a velocity (c) dependent on the medium through which it propagates (for soft tissue, $c = 1540$ m/s). The wavelength (λ) is the distance between two consecutive and equivalent parts. The frequency (ν) is the number of compressions per unit of time expressed in Hertz. The frequency and wavelength are inversely proportional to each other through the velocity of sound ($\nu\lambda = c$). The amplitude is the pressure difference between nadir and peak. In echocardiography, waves are emitted as pulses consisting of wave cycles. Therefore, the spatial pulse length is the distance from the beginning of a single pulse train to its end.

The echocardiographic transducer does not emit ultrasound continuously but rather emits pulses rapidly ($\sim 1,000$ pulses/s) and quickly ($\sim 1 \mu\text{s}$ for every pulse). Therefore, the transducer is operating as a transmitter for an extremely short time (0.1% of the time). During a 30-minute examination, the transducer has transmitted pulses for <2 seconds. When the transducer is not emitting sound waves, it is in its receiver mode awaiting the return of reflected ultrasound.

Eight Equations that Form the Basis of Two-Dimensional and Doppler Echocardiography

Equation 1: The Basis of Image Generation

$$\%R = \{(Z_2 - Z_1) / (Z_2 + Z_1)\}^2 \times 100 \quad [1]$$

where

$\%R$ = percent reflection of ultrasound signal

Z_n = impedance in medium_n = $\rho_n c_n$

ρ_n = density of medium_n

c_n = speed of sound in medium_n

As an ultrasound beam travels through the body, some of its energy will be reflected back to the transducer and some of its energy will continue to be transmitted forward. In considering the amount of reflected energy, it is helpful to consider the concept of momentum, which is the product of mass (m) of an object and its velocity (v) (momentum = mv). A speeding semitractor trailer (high velocity, huge mass) has much greater momentum than a pedaling bicyclist (slow velocity, small mass). Consider the well-known novelty of a set of metallic balls suspended adjacent to each other as a pendulum (Fig. 8.2). An outside ball is drawn away from the stationary balls and is released, striking the stationary balls, resulting in the outside ball on the opposite side to move away from the stationary balls. If the first outside ball were the size of a pea, it would strike the stationary balls and merely bounce away from them. It does not have sufficient momentum (because of relatively small mass) to cause any perturbation in the stationary balls. It is therefore merely reflected backward.

Acoustic impedance is the ultrasound equivalent to momentum; density replaces mass, and speed of sound replaces velocity (21). If the acoustic impedance is the same between two media (the equivalent of a large metallic ball in the example above), ultrasound will be readily transmitted through the media interface; however, a mismatch in the impedance between the two media (the equivalent of a pea-sized ball in the example above) will result in reflection of ultrasound.

Equation 2: The Basis of Image Resolution (Part I)

$$\text{SPL} = n(\lambda) = n(c/\nu) \quad [2]$$

where

SPL = spatial pulse length

λ = wavelength

n = number of cycles in a pulse of ultrasound

c = speed of sound

ν = transmission frequency

Axial resolution (resolution along the axis of the ultrasound beam) of a nonpulsed wave is approximately equivalent to its wavelength. A bat feeding at twilight emits ultrasound waves at a frequency of 100 kHz, which provides excellent resolution for catching insects in air ($\lambda = c/\nu = 330 \text{ m/s} \div 100,000 \text{ cycles/s} = 3.3 \text{ mm}$) but provides an unacceptable resolution if an eccentric bat were to try fatuously to echo-locate cardiac anatomy through soft tissue ($1,540 \text{ m/s} \div 100,000 \text{ cycles/s} = 15.4 \text{ mm}$). With pulsed ultrasound, the axial resolution is dependent on

Figure 8.2. In mechanics, energy transfer is dependent on momentum. A: After an outside ball of equivalent size to the stationary balls is released, it strikes the stationary balls, resulting in movement of the outside ball on the opposite side. The ball has sufficient momentum to cause effective energy transfer to the stationary balls. B: After an outside ball of smaller size is released, it strikes the stationary balls and is reflected off of them. This ball has insufficient momentum to result in energy transfer. Acoustic impedance is the ultrasound equivalent to momentum. In ultrasound, energy transfer is dependent on impedance. If the impedances between two media are similar, ultrasound will be readily transmitted. If there is a mismatch in impedance, ultrasound will be reflected.

Figure 8.3. The axial resolution (resolution along the axis of the ultrasound beam) is dependent on the spatial pulse length (SPL). The shorter the SPL, the better the resolution. Resolution can be no better than $1/2$ of the SPL. **A:** The transducer emits pulses of sound waves (solid line) with a relatively long SPL of SPL_A . This train of pulses can distinguish two objects that are separated by a distance of $1/2 SPL_A$ but not closer because the transducer would not have finished receiving the reflected wave from the proximal object before arrival of the reflected wave from the distal object. **B:** The transducer emits pulses of sound with a shorter SPL of SPL_B . These train of pulses can distinguish two objects that are closer together but still not closer than $1/2 SPL_B$ (reflected waves shown as dashed lines).

having a short spatial-pulse length. This can be achieved by either decreasing the number of wave cycles in an ultrasound pulse or decreasing the wavelength (i.e., increasing the transmission frequency). The best possible axial-point separation resolution is equal to $1/2$ of the spatial-pulse length (Fig. 8.3). Using Equation 2, a 10-MHz transducer emitting a train of three pulsed ultrasonic waves will yield a point separation resolution of approximately 0.46 mm ($3 \times 154,000 \text{ cm/s} \div 10,000,000 \text{ cycles/s}$). A 2.5-MHz transducer will have an approximate resolution of 1.8 mm. The poorer axial resolution of a transducer of this frequency therefore limits its usefulness in evaluating anatomy of smaller magnitude, for example, the luminal diameter of a coronary artery or the diameter of a small septal defect.

Equation 3: The Basis of Image Resolution (Part II)

$$D = (d^2 v) / (4c) \quad [3]$$

where

D = depth of near field
 d = diameter of transducer
 v = transmission frequency of transducer
 c = speed of sound

Lateral resolution is the ability to resolve objects that are perpendicular to the beam axis and is dependent not only on transducer frequency but also on the beam width. For a nonfocused transducer, the ultrasonic beam consists of a near field with narrow beam width and good lateral resolution (the Fresnel zone) and a far field where the beam width diverges rapidly limiting resolution (the Fraunhofer zone) (21). The depth of the near field is extended by increasing the frequency or the footprint diameter of the transducer (Equation 3 and Fig. 8.4).

An example is afforded by imaging a newborn. For the parasternal and apical views, a small-diameter, high-frequency probe is advantageous because the cardiac structures are not at a deep depth and the small footprint can be placed between the acoustically unfriendly ribs. For subcostal imaging, a larger-diameter transducer provides great advantage by extending the near field to the level of the cardiac structures improving their resolution.

Lateral resolution can be improved by focusing, which causes the beam width to narrow more distally where it would otherwise begin to diverge. Focusing can be accomplished by external devices (such as mirrors or lenses) or by electronic means;

Figure 8.4. The lateral resolution (resolution perpendicular to the axis of the ultrasound beam) is dependent not only on transmission frequency but also on the beam width of the transducer. The beam is relatively narrow in the near field of the transducer. In the far field, the ultrasound beam begins to diverge and lateral resolution deteriorates. Transducer A has a relatively small diameter and, therefore, a relatively shallow near field. The diameter of transducer B is larger, thereby extending the near field. Near-field depth can be increased even when using a smaller-diameter transducer if transducer frequency is increased (transducer C). Near-field depth is optimized with transducers having relatively large diameters and emitting ultrasound of high frequency (transducer D). Lateral resolution can also be improved by focusing the transducer crystal; however, focusing has the disadvantage of the beam diverging rapidly beyond the focal zone (transducer E).

however, focusing results in two important disadvantages: (a) the focal zone is closer to the transducer face than the nonfocused near-field zone and (b) the far-field divergence of a focused beam is greater than the divergence of a nonfocused beam.

Equation 4: The Yin–Yang Relationship between Resolution and Penetration

$$L = \mu v z \quad [4]$$

where

L = intensity attenuation loss (in decibels)

μ = intensity attenuation coefficient approximately 0.8 dB/cm/MHz for soft tissue

v = transducer frequency (in MHz)

z = distance traveled in the medium by ultrasound wave (in cm)

The energy of the ultrasound wave is decreased by tissue interactions. Attenuation describes the loss of intensity resulting from scattering (reflection at small interfaces) and absorption (energy transformation) (21). Equation 4 demonstrates that intensity loss is greatest (or penetration is poorest) not only at deeper tissue depths but also when using a transducer with a higher frequency, precisely the frequency needed to enhance resolution (Equations 2 and 3). Thus, echocardiography requires a constant balancing act between optimizing resolution without sacrificing penetration and vice versa.

Equation 5: The Basis of Temporal Resolution

$$F = (c) / (2DNn) \quad [5]$$

where

F = frame rate

c = speed of sound

D = sampling depth

N = number of sampling lines per frame

n = number of focal zones used to produce one image

Motion during 2-D echocardiography is portrayed by rapid presentation of successive single image frames, similar to viewing a motion picture film. A single image frame is generated by successive electronic stimulation of each element in the transducer to initiate an ultrasound pulse, which propagates down (and is received up) successive scan lines (one scan

line typically extends through 1 to 3 degrees of the sector). In addition, the superimposition of a color Doppler sector on the image increases the time for a pulse to propagate down and up a scan line. The time required for the pulse to travel down one scan line to the depth of interest and back to the transducer imposes a restriction on how quickly the next element is stimulated, how rapidly a frame is acquired, and how soon the next frame can be produced. The frame rate (expressed in Hz) quantitates the speed of this process (21).

Temporal resolution can be optimized by narrowing the sector size (of both the image and the color Doppler region), thereby decreasing the number of scan lines, or by decreasing the depth range (Equation 5 and Fig. 8.5). A practical, easy-to-remember rule of thumb to optimize frame rate is to ensure that the subject of interest fills the sector wedge completely, eliminating imaging of superfluous tissue at the lateral and inferior aspects of the sector. Since M-mode and Doppler echocardiography have better temporal resolution, these modalities may be more useful when measuring events which are occurring quickly.

Equation 6: The Doppler Equation

$$v_d = [2v_0(V)(\cos \theta)] \div c \quad [6]$$

where

v_d = the observed Doppler frequency shift

v_0 = the transmitted frequency of sound

V = blood flow velocity

θ = the intercept angle between the ultrasound beam and the direction of blood flow

c = the velocity of sound in human tissue

The Doppler principle states that the frequency of a transmitted wave is altered when the source of the wave is in motion (e.g., the siren on an ambulance racing by a pedestrian). The principle is also applicable when the source of the wave is stationary and the “receiver” of the wave is in motion. The observed change in frequency under these circumstances is termed the Doppler shift, after Christian Johann Doppler, who described this phenomenon in 1842 when studying the light waves emitted with the motion of binary stars. The phenomenon is apparent (in the ambulance example reference above) when the ambulance’s wailing siren is perceived as having an increased pitch as it approaches and decreased pitch as it races away.

A stationary surfer waiting to catch a wave encounters the same number of wave crests per minute as emitted by the source.

Figure 8.5. Two subcostal sagittal images demonstrating the factors that impact temporal resolution (arrows). **A:** The sampling depth is 13 cm, and the sector size is wide, yielding a frame rate of 38 Hz. **B:** The sampling depth has been decreased to 9 cm and the sector scan narrowed so that the image fills the entire sector and the frame rate has increased to 69 Hz.

If the surfer paddles away from the beach toward the ocean, he perceives an increase in the wave frequency because he is swimming toward the wave source. If he reverses his direction and heads to the beach (away from the source), he encounters fewer wave crests. If he moves faster in either direction, the difference between the actual and observed frequency of wave crests (the frequency shift) increases. The only instance in which the actual and observed frequencies coincide is when the surfer is stationary.

In medical ultrasound and echocardiography, the Doppler principle is applied using transmitted sound waves to strike moving red blood cells. Sound waves are transmitted by a stationary transducer, strike red blood cells in motion, and the returning “backscattered” sound pulses are Doppler shifted in frequency in relation to the velocity and direction in which the blood cells are moving. Doppler principles are also applied to evaluate tissue motion by Doppler tissue imaging. In these instances, since tissue moves at a much slower speed than blood, a low pass filter is applied to the returning ultrasound signal to allow the low velocity tissue reflections to pass and the high velocity blood signals to be filtered out.

Doppler ultrasound is used primarily to assess velocity of moving structures, whether it be the velocity of blood flow through the heart and vasculature or the velocity of the ventricular myocardium. It is therefore appropriate to rearrange the Doppler equation to solve for velocity:

$$V = [c (v_d)] \div [2 v_o \cos \theta]$$

As the speed of sound (c) and the transmitted frequency (v_o) are constant, and the frequency shift (v_d) can be very accurately measured, it becomes apparent that the main source of potential error in Doppler estimation of velocity arises from the intercept angle, θ , between the sound beam and the direction of blood/tissue motion. Consider the surfer analogy above. If the surfer were moving toward the ocean (toward the wave source) at an oblique angle, then the “frequency shift” (i.e., the difference between the actual and observed frequency of wave crests) would be less than if he were heading directly into the wave source. The observed velocity is the velocity vector parallel to the insonation beam. The true velocity of his movement would not be known unless we were to account for his oblique travel pattern relative to the wave source. This can be determined by dividing the frequency shift by the cosine of θ (the intercept angle between the wave source and his direction of travel). If the true velocity vector is aligned with the ultrasound beam (i.e., $\theta = 0$), then $\cos \theta$ is one and the observed velocity is the true velocity. However, if the true velocity vector and insonation beam are not aligned, the observed velocity will be smaller than the true velocity, unless angle correction is performed. For intercept angles < 20 degrees, $\cos \theta$ is small, and is not felt to result in significant underestimation of the flow velocity. At greater intercept angles, correction for $\cos \theta$ is needed (Fig. 8.6). In clinical application, Doppler evaluation is generally avoided at higher intercept angles to avoid inaccuracy and the need for angle correction.

Equation 7: The Basis of Aliasing

$$V_{\max} = (c^2) \div [8 v_o D \cos \theta] \quad [7]$$

where

V_{\max} = the maximum measurable velocity of blood

c = the velocity of sound in tissue

v_o = the transmitted frequency of sound

D = depth of interest

θ = the intercept angle between the ultrasound beam and the direction of blood flow

Figure 8.6. Angle correction for Doppler velocity assessment. The measured Doppler velocity is the velocity vector parallel to the line of insonation (dotted line). The velocity of interest, in this case the velocity of red blood cells coursing through the abdominal aorta or the true velocity, is related to the measured velocity by the cosine of the angle, θ , between the direction of flow and the line of insonation. For $\theta > 20$ degrees, the cosine function becomes significantly less than 1, and will result in significant underestimation of the true velocity, V . The Doppler equation allows calculation of the true velocity even when the angle between the insonation beam and the vector of the true velocity is significant by dividing the frequency shift by $\cos \theta$.

If the Doppler sampling rate is not adequate, the frequency of the reflected wave is sampled only intermittently, data must be inferred, and the wave is misinterpreted as having a lower frequency—a phenomenon called aliasing. The phenomenon is apparent in older Western movies when the wheel of a stagecoach is perceived as rotating backwards while the stagecoach is obviously moving forward. The movie consists of a series of stop-action photographs, which when shown one after the other, give the appearance of motion. If the stagecoach moves very fast, the wheel turns very fast and turns too great a revolutionary arc between successive photographs. The problem is solved by decreasing the time between successive photographs so the wheel turns a smaller arc between photographs (Fig. 8.7). Equation 7 demonstrates that the maximum measurable velocity of blood can be increased by decreasing the transducer frequency and/or sampling at a shallower depth. Since the latter is usually not alterable, increasing the aliasing (or Nyquist limit) is achieved by exchanging to a lower frequency transducer.

The phenomenon of aliasing and the value of using lower frequency transducers for sampling higher blood velocities are also understood by contemplating the concept of pulse repetition frequency (PRF) in the context of Equation 6. Since it requires a minimum of two pulses per wave cycle to define frequency unambiguously, the minimum PRF to sample a reflected wave's frequency is twice the Doppler shift. Therefore a more reasonable PRF is achieved by minimizing the Doppler shift. It is clear from Equation 6 that at any given blood velocity and Doppler angle, a lower Doppler shift (i.e., low v_d) is only achieved by reducing transducer frequency (i.e., low v_o).

Equation 8: The Bernoulli Equation

$$\Delta P = \frac{1}{2} \rho (V_2^2 - V_1^2) + \rho \int dV / dt(ds) + R(V) \quad [8]$$

where

ΔP = the pressure difference across an obstructive orifice

V_1 = the flow velocity proximal to the obstruction

Figure 8.7. The principle of aliasing is similar to the phenomenon in old Western movies of a wheel of a stagecoach appearing to rotate backward when the stagecoach is obviously moving forward. The movie consists of a series of stop-action photographs which when placed in sequential order give the appearance of motion. If the series of photographs are captured at too low a frequency (top row) any spoke on the wheel (e.g., the highlighted, bold spike), will appear to be rotating backward (in this case, appearing to rotate 90 degrees counterclockwise each time an image is captured). It is only when the frequency of snapping photographs is high enough (bottom row), that the true forward rotation of the wheel is appreciated (in this case, rotating 90 degrees clockwise each time an image is snapped).

V_2 = the flow velocity distal to the obstruction
 ρ = the mass density of blood = 1,060 kg/m³
 dV = change in velocity over time (dt)
 ds = distance over which change in pressure occurs
 R = viscous resistance in blood vessel
 V = velocity of blood flow

The first term, $\frac{1}{2} \rho (V_2^2 - V_1^2)$, represents convective acceleration through the flow orifice. This portion of the equation becomes $4 (V_2^2 - V_1^2)$ when substituting the blood density of 1,060 kg/m³ into the equation, multiplying by $\frac{1}{2}$ and, multiplying by the conversion factor of 0.0075 which converts kg/m/s² (a pascal) to mm Hg. In addition, in most clinical conditions, the proximal flow velocity is < 1 m/s, and is considered negligible. Thus, the first term can be simplified as $4V_2^2$. The second term $(\rho dV/dt (ds))$ describes energy expended to accelerate fluid at the onset of flow; clinical measurements are usually made at peak flow, thus, this term can be assumed to be zero. The third term $R (V)$ describes energy lost overcoming viscous friction along the walls of the vessel, and is felt to be of little impact in most clinical circumstances. Therefore, the Bernoulli equation can be simplified, acknowledging the assumptions above:

$$\Delta P = 4V_2^2 \quad [9]$$

It is important to understand that when the assumptions used to simplify the Bernoulli equation may not apply, the approach to estimating pressure gradients may need to be modified. A common example of such an instance is in estimation of pressure drops where the proximal velocity (V_1) is greater than 1 m/s such as across an aortic coarctation, stenotic and regurgitant semilunar valves (where the regurgitant volume may result in an increase in V_1), multiple obstructions in series, and in the setting of high cardiac output. Viscous resistance may not be negligible in other circumstances where the obstruction is long and narrow (22) such as across Blalock-Taussig shunts, or across tunnel-type obstructions, for example, tubular obstruction of the left ventricular outflow tract.

THE EXAMINATION

General Considerations

Echocardiographic Windows

There are four major echocardiographic windows to the heart (Fig. 8.8): (a) parasternal, (b) apical, (c) subcostal, and (d) suprasternal notch. (A fifth window, the right parasternal window, obtained with the patient in a right lateral decubitus position, is used for obtaining an accurate Doppler gradient in patients with aortic valve stenosis.) The examination usually is performed in this same order, beginning with the least noxious (parasternal) window and finishing with the potentially most noxious (suprasternal notch) window. In complex cases associated with abnormal situs or cardiac position, the examination may alternatively begin with the apical or subcostal windows so that the echocardiographer can become oriented for the other views.

Parasternal and apical imaging is performed with the patient in a left lateral decubitus position. A dropout mattress is essential for obtaining the apical view. During subcostal imaging, the patient lies supine, sometimes flexing the knees, thereby relaxing the abdominal muscles. Suprasternal imaging is performed with a roll under the shoulders to extend the neck. When using the right parasternal view for Doppler interrogation of valvar aortic stenosis, the patient should be positioned in a right lateral decubitus position.

Planes of the Heart and Technique of Sweeping: Thinking in Three Dimensions

Three-dimensional (3-D) imaging is enjoying more routine use for clinical purposes. However, the challenge and essence of pediatric echocardiography continue to be acquiring all the necessary 2-D images, mentally synthesizing them into a 3-D model, and conveying this 3-D representation to others by narrative or visual tools.

Figure 8.8. There are four main echocardiographic windows: (a) parasternal, (b) apical, (c) subcostal, and (d) suprasternal notch. The parasternal and apical windows are obtained with the patient in a left lateral decubitus position using a drop-out mattress. Subcostal images are obtained with the patient supine and sometimes with the knees flexed. Suprasternal notch images are obtained with a roll under the shoulders so that the neck is hyperextended. Additional windows include the right parasternal with the patient in a right lateral decubitus position useful for the Doppler interrogation of valvar aortic stenosis and the right apical view along the right anterior axillary line used when imaging patients with dextrocardia.

The spatial location of any part of an object is defined and understood by considering it in relation to the three planes (transverse (axial), sagittal, and coronal) in which the object exists (Fig. 8.9). Each of the four standard echocardiographic windows affords the opportunity to image the heart from one or more of these three planes. From the parasternal window, the long (sagittal) and short (axial) planes are shown. From the apical and subcostal windows, the four-chamber (coronal) and two-chamber (sagittal) planes are demonstrated. Finally, from the suprasternal notch window, the sagittal and axial axes of the upper thoracic vasculature are imaged. Sweeping the transducer through the nearly parallel planes within each of the acoustic windows mimics the ability of other imaging modalities such as magnetic resonance to obtain parallel “slices” within a given plane (Fig. 8.10). With these techniques, the spatial relationships become clear, and the 3-D mental reconstruction of the heart becomes possible.

Optimizing the Doppler Examination

The robustness of Doppler echocardiography as a tool for evaluating cardiac physiology is only manifest when its practitioners exhibit precise and diligent technique. Doppler spectral envelopes must be sharp and free of feathering. A sharp envelope is first achieved by aligning the ultrasound beam as parallel to the flow as possible. Traditionally, color Doppler is used before application of pulsed or continuous wave Doppler to determine the precise location and direction of a jet. The transducer position on the chest is then moved accordingly so that the flow is directed either exactly toward or opposite to it. The best transducer position for the Doppler examination may therefore be offset from the most ideal position for 2-D imaging. Not only the spectral display but also the audio component from the Doppler signal is often helpful in determining if one is localized in the vena contracta and parallel to flow. Second, the practitioner must be careful to avoid overgaining the

Figure 8.9. A: There are three imaging planes of the body: sagittal, coronal, and transverse. B: There are also three imaging planes of the heart. The cardiac imaging planes are rotated leftward and anterior because the heart's axes are rotated leftward and anterior relative to the body's.

Figure 8.10. The family of sweeps for each of the imaging planes of the heart. **A:** The parasternal long-axis sweeps consist of the rightward tricuspid valve view (1), the standard long-axis plane (2), and the leftward pulmonary valve view (3). **B:** The parasternal short-axis sweeps consist of the superior basal view (1), the standard plane at the level of the mitral valve (2), and the inferior papillary muscle view (3). **C:** The apical sweeps consist of the anterior five-chamber view (1), the standard apical four-chamber view (2), and the posterior coronary sinus view (3). **D:** The subcostal coronal sweeps consist of the posterior coronary sinus view (1), the standard four-chamber view (2), the anterior left ventricular outflow tract view (3), and the extremely anterior right ventricular outflow tract view (4). (*Continued*)

spectral display which can cause indistinct envelopes. Third, the spectral display of interest should fill as much of the screen as possible by shifting the baseline up or down and decreasing the Doppler scale. In this way, the envelope is made as large as possible minimizing the effect of imprecise Doppler envelope planimetry (Fig. 8.11). Fourth, tracing the Doppler envelope must be careful, precise, and steady. The operator must know if a trace of modal velocity (for continuity equation) or of peak (or mean) velocity (for pressure gradients) is most appropriate (Fig. 8.12).

Color Flow Doppler

With its development in the 1980s, color flow Doppler revolutionized echocardiography by providing an efficient overview of flow across a relatively vast region of interest making it extremely valuable in screening for normal and abnormal flows across valves, vessels, and septa. The color Doppler modality interrogates flow with multiple pulsed Doppler sample volumes placed successively along multiple scan lines. For each sampling gate, the baseline frequency is compared to the

Figure 8.10. (Continued). E: The subcostal sagittal sweeps consist of the rightward systemic venous return view (1), the slightly leftward left ventricular outflow tract view (2), the leftward right ventricular outflow tract view (3), and the extremely leftward ventricular view (4). F: The suprasternal long-axis sweeps consist of the standard aortic arch view (1), the rightward superior vena caval view (not shown), and the leftward left pulmonary artery view (2). G: The suprasternal short-axis sweeps consist of the very anterosuperior strap vessels view (not shown), the anterosuperior vena cava and innominate vein view (1), the standard right pulmonary artery and left atrial view (2), and the posterior descending aorta view (not shown). Even though these imaging planes are defined and illustrated here as discrete planes, the technique of sweeping is a process that allows acquisition of dozens of imaging planes tangential to these. The technique of sweeping through these imaging planes in orthogonal views is critical to understanding the 3-D anatomy. AO, aorta; CS, coronary sinus; DAO, descending aorta; EUS, Eustachian valve; IVC, inferior vena cava; LA, left atrium; LPA, left pulmonary artery; LV, left ventricle; MB, moderator band; MV, mitral valve; PA, pulmonary artery; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; SVC, superior vena cava; TV, tricuspid valve. (Reprinted from Snider AR, Serwer GA, Ritter SB, eds. *Echocardiography in Pediatric Heart Disease*. 2nd ed. St. Louis, MO: Mosby-Year Book, 1997:27–52, with permission from Elsevier.)

received frequency. Pixels in the image are arbitrarily assigned a color (red for flow toward the transducer and blue for flow away from the transducer) and the color intensity is based on the magnitude of the mean velocity. The color Doppler scale should be actively manipulated throughout the examination—using low velocity scales when interrogating venous velocities (e.g., those across/in antegrade atrioventricular valves, atrial

septum, cavopulmonary shunt, and systemic and pulmonary venous velocities) or velocities generated from lower pressure gradients (e.g., in the coronary arteries, across a large VSD or patent ductus arteriosus [PDA]) and high velocity scales when interrogating arterial flows or flows generated from high pressure gradients (e.g., atrioventricular valve regurgitation, restrictive VSD or PDA). The examiner must actively think

Figure 8.11. Mitral valve Doppler spectral profile recorded with (A) inappropriate and (B) appropriate scale and baseline shift. It is important to fill as much of the Doppler display area, thereby enlarging the Doppler spectral profile as much as possible thus minimizing error in measurement (B).

about and anticipate expected physiology during the study so that the color scale is appropriately adjusted (Fig. 8.13). For example, in a toddler being evaluated for a suspected ventricular septal defect (VSD), interrogation of the septum with a high color Doppler scale is appropriate. However, using such a high color scale in the investigation for a VSD in a newborn would likely miss the low velocity shunt flow since the shunt is driven by a very low pressure gradient due to the normally elevated pulmonary vascular resistance in the newborn period. The examiner would need to interrogate the ventricular septum with a low velocity color Doppler scale in this instance. These flows then need to be more carefully and precisely interrogated and quantitated with either pulsed or continuous wave Doppler. Because of the massive amount of data, a color Doppler sector should be kept as narrow as acceptable to improve accuracy and/or temporal resolution (see Section Equation 5: The Basis of Temporal Resolution)

Pulsed Wave Doppler

Pulsed wave Doppler, along with continuous wave Doppler, is the principal echocardiographic tool for evaluating cardiovascular physiology. Pulsed Doppler causes the transducer to

Figure 8.12. Mitral valve Doppler spectral profile demonstrating the difference between a “peak” velocity trace (green on the left waveform) and modal velocity trace (yellow on the right waveform). The “peak” velocity trace follows the outside edge of the Doppler spectral contour while the modal velocity trace follows the midline of the contour. “Peak” velocity traces are used to obtain peak and mean pressure gradients across valves and orifices. Modal velocity traces are used in the continuity equation and in calculation of cardiac output. Note that there can be a potentially large difference in the values obtained from a “peak” and modal velocity trace. (e.g., 31% difference in the two velocity time integrals (VTI) in this case)

alternately transmit and receive short ultrasound bursts. The time between transmission and reception allows calculation of the depth of the signal or “range-gating” which provides the operator with the Doppler frequency shift at a specific location. A disadvantage with the technique is that the maximal detectable frequency shift is limited—the Nyquist limit (see Section Equation 7: The Basis of Aliasing). However, the Nyquist limit can be extended by shifting the baseline of the spectral display, exchanging to a lower frequency transducer, or moving to a different imaging plane so that the structure of interest is at a shallower depth if possible. High-PRF is a technique in which volleys of pulses of ultrasound are sent before reception of prior pulses. This technique increases the Nyquist limit but causes some range ambiguity.

Continuous Wave Doppler

With the continuous wave Doppler modality, the transducer is continuously transmitting and receiving ultrasound signals. The disadvantage of this process is the absence of range gating, but a major advantage is that the sampling rate is infinite so there is no longer a limit to the maximal frequency shift. The spectral display consists of a composite of signals with the maximal velocity representing the peak velocity at any depth in the plane of the ultrasound beam. Lower velocities are often visible within the spectral envelope allowing calculation of “corrected gradients” in which the lower proximal velocity (V1) is subtracted from the higher distal velocity (V2) as is performed for the evaluation of a gradient across an aortic coarctation.

Approach to the Pediatric Patient

A cheerful environment is important in relieving anxiety. Bright-colored rooms filled with toys and stuffed animals capturing the environment of the patient’s own bedroom can make the child feel more comfortable. Rooms should be equipped with television and DVD players so that patients can be entertained during the examination. Warm ultrasound gel also helps in reducing stress. For infants, light dimmers and an infant warmer will facilitate a comfortable environment. Formula should be available for further comforting of infants.

Figure 8.13. Series of four images demonstrating inappropriate and appropriate color aliasing limits during the echocardiographic examination. Throughout an echocardiographic examination the echocardiographer must actively decrease and increase the color aliasing limit depending on the expected velocity of the color jet being interrogated. For example, in evaluating high-velocity jets such as mitral insufficiency, color aliasing limits should be high as in this apical four-chamber view shown in (A) where the velocity limit is 81 cm/s. This provides a clean, crisp, and interpretable display of the mitral insufficiency flow. Inappropriate low color aliasing limit as in (B) (39 cm/s) produces an indistinct display of the mitral insufficiency jet. On the other hand, when evaluating a low-velocity color jet such as a patent foramen ovale (PFO) the color aliasing velocity should be lower to enhance recognition and display as in the subcostal image (C) where the aliasing velocity is 46 cm/s. If the aliasing velocity is set too high (79 cm/s in this example), detection of the low-velocity PFO jet may be impossible (D).

Even in a nonthreatening environment, patients over 6 months and under 3 years of age often require sedation. Presedation guidelines delineating the fasting requirements and describing the sedation procedure need to be sent to parents before the echocardiography visit. Chloral hydrate (75 to 100 mg/kg administered orally) or pentobarbital (5 mg/kg orally) are commonly used agents for sedation. In order to remain compliant with increasingly strict regulations from the Centers for Medicare and Medicaid Services, many pediatric laboratories are electing to employ anesthesiologist and/or nurse anesthetists for the administration and monitoring of conscious sedation. Monitoring and resuscitation equipment should be available in each room in the event of an adverse reaction or complication.

Echocardiography: Robust Phenotyping Tool

Echocardiography represents a “physiologic microscope” which singularly provides phenotypic observations on an

“experimental preparation” (the pediatric cardiovascular system) with minimal interference from external noxious influences. Therefore, unique opportunities to evaluate both cardiovascular anatomy and physiology are afforded that are not available with other imaging modalities, for example, during magnetic resonance imaging when the patient may have to endure an examination of prolonged duration or during catheterization when the heart is probed with catheters.

Defining Anatomy: Segmental Approach

The echocardiographic examination is performed, and the interpretation is presented using a segmental approach (23–27) which requires complete definition of eight features of cardiac anatomy (Table 8.1). This is a two-step process. The first is the proper identification of a structure which requires the abilities of imaging and recognizing the specific features of

TABLE

8.1

Segmental Approach to Defining Cardiac Anatomy by Echocardiography

Anatomic Feature	Diagnostic Possibilities
Thoracoabdominal situs	Solitus Inversus Ambiguous
Cardiac position	Levocardia Mesocardia Dextrocardia
Atria	Solitus (S) Inversus (I) Ambiguous (A)—bilateral right- and left-sidedness
<i>Atrioventricular connection</i>	Concordant Discordant Atresia Double inlet Common Straddling Criss-cross
Ventricles	d-looped (D) l-looped (L) x-indeterminate
Conus	Subpulmonic Subaortic Bilateral Absent or very deficient
<i>Ventriculoarterial connection</i>	Concordant Discordant Double outlet Single outlet
Great vessels	Solitus (S) Inversus (I) Transposed (D, L, A) Side-by-side

A complete segmental description of the heart by echocardiography begins by defining these eight features which include the three segments of the heart (shown in bold) and the two junctional segments (shown in italics). The letters in parentheses following the diagnostic possibilities for the three cardiac segments are frequently used as abbreviated three-letter descriptors of these segments: the first initial describing atrial situs, the second describing ventricular topology, and the third describing the great vessel relationship. For example, (S, D, S) describes a normal heart, while (I, L, I) describes mirror image dextrocardia. Following description of the morphology, intrinsic (e.g., pulmonary stenosis), myocardial (e.g., hypertrophic cardiomyopathy), septal (e.g., tetralogy or Fallot), orientation (e.g., criss-cross heart), defect (e.g., ventricular septal defect or aortopulmonary window) pathology is described.

each cardiac structure. The second is determining the spatial and physiologic relationships of a properly identified structure to the other structures (both cardiac and noncardiac) in the thoracoabdominal cavity. Accurate morphology can be accomplished definitively only by imaging chamber septal structures. Next, other malformations (e.g., cardiac shunts, valve function) and physiology (biventricular function, chamber sizes, pressure estimates) are described. To ensure that no anatomy or physiology is left undescribed, it is helpful during both the

performance and interpretation of the examination to imagine the course of a red blood cell traveling through the heart, beginning in the systemic veins and terminating in the systemic arteries.

Abdominal Situs and Cardiac Position

Abdominal situs is best determined from a transverse view of the abdomen below the diaphragm (Fig. 8.14). In this view the positions of the liver and the gastric bubble can be ascertained. In patients with abdominal situs solitus, the stomach is on the left and the liver is on the right. In patients with abdominal situs inversus, the opposite is true.

The position of the heart in the thoracic cavity is identified most easily from an apical four-chamber or subcostal coronal view. The position of the transducer on the chest from where a standard apical four-chamber view is obtained defines the position of the cardiac apex. From the subcostal coronal view, the side of the cardiac apex is determined (Fig. 8.15). The normal position of the heart in the left chest is termed levocardia. The mesocardic term refers to a cardiac position over the patient's midline.

Dextrocardia indicates that the heart lies in the right side of the chest. There are three main categories of dextrocardia. The first is termed dextroposition and refers to a condition in which the heart is pushed into the right chest by either a mass in the left chest (e.g., diaphragmatic hernia) or deficiencies in right-sided chest structures. The apex remains pointed to the left, atrial situs, ventricular topology, and great vessel relationships are normal, and cardiac pathology, if any, is not complex. In the other two types of dextrocardia, termed dextroversion and mirror-image dextrocardia, the apex is pointed to the patient's right. Dextroversion refers to a condition in which there is atrial situs solitus with a rightward-pointing apex. Ventricular inversion (atrioventricular discordance) and associated pathology similar to that seen in congenitally corrected transposition of the great vessels is frequently associated. Mirror-image dextrocardia is a condition with atrial situs inversus and a rightward-pointing apex. These patients' anatomy is "mirror image" to that of a patient with levocardia and atrial situs solitus and their anatomy is best appreciated by imagining a mirror placed on a patient with levocardia and situs solitus at the patient's midline in a sagittal position. In this way, one appreciates that structures that are normally far left (e.g., left ventricle) are in a far right position in a patient with mirror image dextrocardia. Structures that are closer to the midline (e.g., the superior vena cava [SVC]) are in a midline position in a patient with mirror image dextrocardia. There may be major and complex pathology associated with mirror image dextrocardia. However, in situs inversus totalis (a condition in which all body organs are on the contralateral side of the body from which they usually reside), the heart may be completely normal.

When evaluating a patient with any of these three types of dextrocardia, the echocardiographer must maintain left/right conventions rather than attempting to make the image look familiar. Specifically, the echocardiographer must remain true to the established echocardiographic convention that the **right** side of the screen/monitor in the parasternal short-axis, apical four-chamber, and subcostal coronal view is always the **left** side of the patient. This convention is maintained by the echocardiographer rotating the transducer so that the "orientation mark" on the transducer is pointing to the patient's left in these imaging planes. There will be a tendency (which must be resisted) for the echocardiographer to rotate the transducer to an unusual or atypical position to attempt to make the image look "normal." In some instances, this is problematic because it could reverse the left/right echocardiographic conventions.

Figure 8.14. Subcostal transverse abdominal views in a patient with abdominal situs solitus (A) and in a patient with abdominal situs inversus (B). With abdominal situs solitus, the liver is on the patient's right and the stomach is on the left. In abdominal situs inversus, the liver is on the left and the stomach is on the right. A, anterior; Ao, descending abdominal aorta; IVC, inferior vena cava; R, right.

Venous Return and Atria

Situs

The fact that an atrial chamber is on the patient's right or left or that it receives a particular venous structure does not allow a conclusion regarding atrial morphology. Atrial situs can be deduced only by evaluation of the atrial appendages and the septal structures.

The atrial appendages are consistently committed to their respective atria and are distinctly morphologically different. The right atrial appendage is short, fat, and broad-based and best seen in the subcostal sagittal view, as well as the parasternal long-axis view (Fig. 8.16A). The left atrial appendage is long, thin, and narrow-based and best seen in the parasternal short-axis and apical four-chamber views (Fig. 8.16B). The atrial appendages have pectinate muscles (raised parallel ridges resembling the teeth of a comb) which also help make them distinct. These muscles of the right atrial appendage extend into the right atrium (RA) whereas the pectinate muscles of the left atrial appendage are confined to the appendage and do not extend into the atrium (28,29).

The unique septal structures of the RA are the embryonic valves—Eustachian and Thebesian—seen in the subcostal coronal and sagittal views. The unique left atrial septal structure is the flap valve seen in the apical and subcostal coronal and sagittal views (Fig. 8.17). In heterotaxy syndrome with bilateral right- or left-sidedness and common atrium, the atrial septal structures will not be obvious and atrial situs will be indeterminate or ambiguous.

SYSTEMIC VEINS AND RIGHT ATRIUM

The innominate veins are identified in the suprasternal short-axis view. Both innominate veins are identified and traced downstream as they join to form the right superior vena cava (RSVC) which, in turn, is followed to its entrance into the heart (Fig. 8.18). The left innominate vein is traced upstream to identify a possible left superior vena cava (LSVC) (Fig. 8.19). Alternatively, a suprasternal notch long-axis view can be swept leftward from the aortic arch to demonstrate a LSVC in its long axis (Fig. 8.20). These maneuvers are particularly important in (a) any patient undergoing surgical repair

Figure 8.15. Subcostal coronal views of a patient with levocardia (A) and a second patient with dextrocardia (B). In the patient with dextrocardia, the apex of the heart is pointing to the patient's right. The patient has mirror image dextrocardia so that the morphologic left atrium (LA) and left ventricle are on the patient's right and the morphologic right atrium (RA) and right ventricle (RV) are on the patient's left. The patient also has a small midmuscular ventricular septal defect (block arrow). R, right; S, superior.

Figure 8.16. Echocardiographic imaging of the atrial appendages. **A:** The right atrial appendage (RAA) is broad based and is best seen in the subcostal plane and, as shown here, in the parasternal long view swept rightward. **B:** The left atrial appendage (LAA) is long and thin and is best seen in the parasternal short-axis view (**B**). A, anterior; Ao, aorta; I, inferior; LA, left atrium; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

using cardiopulmonary bypass since a surgeon may have to cannulate both SVCs (when present) in the absence of a left innominate vein and (b) the newborn with single-ventricle physiology, who will undergo eventual bilateral bidirectional cavopulmonary anastomoses in the presence of bilateral SVC without an innominate vein. In patients with unexplained cyanosis or systemic emboli or with absent innominate vein without dilated coronary sinus, the presence of a LSVC draining directly into the left atrium (LA) should be investigated. This may require using agitated saline contrast (see Section Contrast Echocardiography).

The inferior vena cava (IVC) is identified in the subcostal transverse abdominal and subcostal coronal and sagittal views (Fig. 8.14). Anyone performing cardiac catheterization needs to be alerted for interruption of the IVC. This is apparent in the transverse abdominal view where a large venous vessel immediately posterior to the aorta (the azygous or hemiazygous vein) is seen and there is notable absence of an IVC candidate anterior to the aorta (Fig. 8.21).

The entrance of the coronary sinus into the RA can be seen in the subcostal coronal and the apical four-chamber views. The size and possible unroofing of the coronary sinus can be

assessed in a posterior sweep from the standard apical four-chamber and parasternal long-axis views.

ATRIAL SEPTUM

The atrial septum is examined in the subcostal coronal and sagittal views. With the increasing responsibility of echocardiographers to define atrial septal rims for device closure of atrial septal defect (ASD), the complexity of the atrial septum is gaining a new appreciation. The size of an ASD, as well as the degree of remaining atrial septal rim tissue for anchoring of possible ASD closure device and total atrial septal length for maximum possible diameter for said device, are best evaluated by using both these views to give information from two mutually orthogonal planes. In addition, the rim between aorta and defect can be assessed in the parasternal short-axis view.

Superior and inferior vena caval sinus venosus defects are best seen in the subcostal sagittal view. The transducer should be swept gradually and deliberately posterior and rightward to investigate for possible associated partial anomalous pulmonary venous return. Secundum ASDs are best seen in the same imaging planes. The ostium primum defect

Figure 8.17. Subcostal sagittal views demonstrating Eustachian valve (**A**) and flap valve (block arrow in **B**). These unique septal structures are the most reliable method for defining the morphologic right and left atrium (RA and LA), respectively. The color panel of Figure B demonstrates a small left-to-right shunt from the LA to the RA through the patent foramen ovale caused by the flap valve. A, anterior; I, inferior; IVC, inferior vena cava; P, posterior; RPA, right pulmonary artery; S, superior; SVC, superior vena cava.

Figure 8.18. Suprasternal notch short-axis view demonstrating the left brachiocephalic vein draining into the right superior vena cava (SVC) in a patient with total anomalous pulmonary venous return of the supracardiac type. The pulmonary veins drained to a pulmonary vein confluence immediately superior to the roof of the LA. Pulmonary venous flow then continued through a vertical vein, the left brachiocephalic vein and the SVC resulting in dilatation of the latter two structures. R, right; RPA, right pulmonary artery; S, superior; SVC, superior vena cava.

is related to the crux of the heart and is therefore best seen in the apical view. The coronary sinus defect is visualized by sweeping the transducer posterior from the standard apical four-chamber view.

PULMONARY VEINS AND LEFT ATRIUM

The pulmonary veins are identified most easily from the suprasternal short-axis plane (Fig. 8.22). Alternatively, the pulmonary veins can be visualized from the parasternal short-axis and apical four-chamber views. An extreme rightward sweep (tilt right from the SVC, RA, IVC views) in the subcostal sagittal plane consistently reveals the right upper pulmonary vein. Parasagittal imaging from the bicaval view can show the right

Figure 8.19. High suprasternal notch short-axis view demonstrating not only the normal anatomy and relationships of the right superior vena cava (SVC), ascending aorta (Ao), and main pulmonary artery (MPA), but also the additional finding of a left superior vena cava (LSVC) in cross section just leftward of the MPA. LPA, left pulmonary artery; R, right; RPA, right pulmonary artery; S, superior.

Figure 8.20. Hybrid suprasternal notch oblique axis view of left superior vena cava (LSVC), which in this patient is draining directly into the roof of the left atrium (LA) due to complete unroofing of the coronary sinus. A, anterior; LLPV, left lower pulmonary vein; LUPV, left upper pulmonary vein; RA, right atrium; S, superior.

pulmonary veins (with a rightward sweep) and the left pulmonary veins (with a leftward sweep) in cross section as they course into the LA. Color Doppler with a low velocity aliasing limit can aid in visualizing the individual pulmonary veins (30). Anomalous pulmonary venous pathways, the confluences from which they emanate, and the entrances of the pulmonary veins into the confluences should be investigated from the suprasternal short axis view (supracardiac drainage), parasternal and apical views (cardiac drainage), and subcostal coronal and sagittal views (infracardiac drainage). Unlike systemic venous anomalies, in which color Doppler demonstrates flow coursing toward the heart, these anomalous pulmonary venous pathways will have color Doppler flow coursing away from the heart, often the first sign that makes an echocardiographer aware of this condition.

The LA is best evaluated in the apical four-chamber and the subcostal coronal and sagittal views. Membranes (e.g., supra-valvar stenosing mitral ring and cor triatriatum) are identified in the apical four-chamber view. The diagnostic relationship of these membranes relative to the left atrial appendage (i.e., membrane of cor triatriatum upstream from the LA appendage

Figure 8.21. Subcostal transverse abdominal view demonstrating the features of interrupted inferior vena cava (IVC). There is no venous structure identified anterior to the aorta. Instead, there is a venous structure which is adjacent and slightly posterior to the aorta. The structure is also rightward of the aorta indicating that it is an azygous continuation of interrupted IVC.

Figure 8.22. Suprasternal notch short-axis view with color Doppler demonstrating the four pulmonary veins draining normally into the left atrium. Ao, ascending aorta; LA, left atrium; LLPV, left lower pulmonary vein; LUPV, left upper pulmonary vein; MPA, main pulmonary artery; RLPV, right lower pulmonary vein; RUPV, right upper pulmonary vein; R, right; S, superior; SVC, superior vena cava.

orifice and membrane of supravalvar stenosing mitral ring downstream in the mitral valve funnel itself) is visualized from the apical four-chamber view.

Atrioventricular Connection

TYPE

The septal structures of the atrioventricular valves serve as the only consistent feature allowing morphologic diagnosis. The tricuspid valve has an intimate relationship with the ventricular septum (i.e., septophilic), with multiple chordal attachments emanating from its septal leaflet, seen best in the apical four-chamber view. On the other hand, the mitral valve has no chordal attachments with the ventricular septum (septophobic), and all of its attachments course to the left ventricular free wall (Fig. 8.23). In addition, the hinge point of the septal leaflet of the tricuspid valve is inferior to the hinge point of the anterior leaflet of the mitral valve. Because each atrioventricular valve is associated with its appropriate ventricle (i.e., tricuspid valve with right ventricle, mitral valve with left ventricle), the atrioventricular connection can be determined as concordant (RA to right ventricle and LA to left ventricle) or discordant (RA to left ventricle and LA to right ventricle). Atrietic atrioventricular connections are easily identified in the apical and subcostal views. The relationship of the atrioventricular valves to each other in double-inlet connections are explored in the parasternal views. The five leaflets of the common atrioventricular valve (superior/anterior bridging, right superior, right mural, inferior/posterior bridging, and left mural) are best seen in a right anterior oblique subcostal view (midway between the coronal and sagittal views). In this view, the presence or absence of a tongue of tissue connecting the two bridging leaflets should be identified first to allow the establishment of a complete (absent connecting tissue) or partial (present connecting tissue) atrioventricular septal defect. Then the degree of bridging of the superior leaflet and its attachments are identified, allowing for Rastelli classification (Fig. 8.24). Straddling and criss-cross connections are seen in the apical four-chamber and subcostal views. A straddling atrioventricular valve (valve attachments to contralateral ventricle) must be distinguished from mere overriding (valve annulus partially displaced over the ventricle) in these views. Criss-cross atrioventricular relationships necessitate deliberate and slow sweeping of the transducer anteriorly and posteriorly in the

Figure 8.23. Apical four-chamber view in a patient with ventricular inversion with congenitally corrected transposition of the great vessels {S, L, L}. The left-sided atrioventricular valve has attachments to the ventricular septum, whereas the right-sided valve does not, allowing diagnosis of a left-sided tricuspid valve and a right-sided mitral valve. In addition, the septal hinge point of the tricuspid valve is inferior to that of the mitral valve, which is another distinguishing feature of a tricuspid valve. There is a moderator band near the apex of the left-sided ventricle, further defining this ventricle as a morphologic right ventricle. I, inferior; LA, left atrium; RA, right atrium; S, superior.

subcostal coronal or superiorly and inferiorly in the parasternal short-axis views with careful, simultaneous observation of each valve's upstream atrium and downstream ventricle.

TRICUSPID VALVE

The tricuspid valve is examined in the parasternal long-axis plane (sweeping right from the standard plane), the apical four-chamber view, and the subcostal coronal and sagittal views. The septal leaflet and its attachments to the interventricular

Figure 8.24. The subcostal oblique view (a hybrid between coronal and sagittal views) of a common atrioventricular valve. The five leaflets of the common atrioventricular valve are shown including the superior and inferior bridging leaflets. The commissure of the superior bridging leaflet attaches to the inferior portion of the outlet septum identifying this as a Rastelli type A atrioventricular septal defect. There is a well-defined left mural leaflet between the papillary muscles which are well spaced. Right accessory and right mural leaflets can be seen in the right ventricular portion of the common valve. LV, left ventricle; RV, right ventricle; S, superior.

septum are best seen in the apical four-chamber view. Also, in this view, the posterior leaflet (with a slight posterior sweep) or the anterior leaflet (with a slight anterior sweep) is seen on the lateral portion of the right ventricular wall. The anterior leaflet and its attachments to the conal papillary muscle (Lancisi) are best visualized in the subcostal coronal view sweeping anteriorly.

In the evaluation of Ebstein anomaly, the degree of atrialization of the right ventricle is assessed from the apical four-chamber view. From here, the septal attachments of the septal leaflet are appreciated. The posterior mural leaflet is seen with a slight posterior sweep from the apical four-chamber view. A portion of the anterior mural leaflet can be seen with an anterior sweep from the apical four-chamber view but the subcostal coronal view is required to visualize the displacement of the anterior leaflet into the right ventricular outflow tract and the degree to which it obstructs it. The tricuspid valve annulus size, which is important to assess in conditions of right ventricular hypoplasia (e.g., pulmonary atresia with intact ventricular septum) and conditions of right ventricular volume overload (e.g., postoperative tetralogy of Fallot with pulmonary regurgitation or hypoplastic left heart syndrome after Norwood), should be evaluated in the apical four-chamber view.

MITRAL VALVE

The mitral valve is visualized in the parasternal, apical four-chamber, subcostal coronal, and sagittal views. The size of the mitral annulus, which is important in determining suitability for biventricular repair in cases of relative left-sided hypoplasia, should be performed in the orthogonal planes of the parasternal long-axis and apical four-chamber views. The papillary muscles, important to assess for repair of complete atrioventricular septal defect and for diagnosing parachute mitral valve, are best visualized in the parasternal short-axis and subcostal sagittal sweeps. Mitral stenosis is assessed in the parasternal long-axis and the apical four-chamber views, where the degree of leaflet excursion can be seen clearly. Mitral valve prolapse is best identified in the parasternal long-axis and apical four-chamber views. Clefting of the mitral valve and double orifice mitral valve are usually seen in the parasternal short-axis sweep.

Ventricles

VENTRICULAR MORPHOLOGY

During embryologic development, the heart begins as a straight tube anchored cephalad by the truncus arteriosus and caudad by the sinus venosus. The tube undergoes differential and rapid growth in its midsection which, because of the anchoring, forces it to bend to the right or the left. Bend to the right results in the right ventricle developing to the right and the left ventricle to the left (D-looping). Bend to the left results in the opposite situation (L-looping). Definition of the embryologic type of ventricular looping first requires clear identification of ventricular morphology. The septal structures once again provide the definitive criteria for this evaluation. The first criterion is the type of atrioventricular valve entering the ventricle (see preceding section on Atrioventricular Connection, Type). The right ventricle also can be identified by its coarse, large, and extensive trabeculations along the septum and free wall. One of these trabeculations, the moderator band, is particularly prominent running transversely from free wall to septum in the inferior third of the right ventricular cavity in the apical view (Fig. 8.23). Once ventricular morphology has been established, the ventricular looping is determined. This is performed by imagining one is standing in the right ventricle facing the right ventricular face of the interventricular septum. The palm of one hand is placed against the septum. The looping is determined by which of the two hands allow the thumb to point into the atrioventricular valve and the fingers to point into the outflow tract. If the right hand meets these criteria, the ventricles are D-looped. If the left hand meets these criteria, the ventricles are L-looped.

RIGHT VENTRICLE

The size of the right ventricle and its relative contribution to the ventricular apex in conditions such as complete atrioventricular septal defect and pulmonary atresia with intact ventricular septum are best assessed from the apical four-chamber view. Because the three portions of the right ventricle (inlet, trabecular, and conus) do not lie in a single plane, visualization of the entire right ventricular cavity requires sweeping of the transducer through multiple planes in the subcostal coronal and sagittal views.

VENTRICULAR SEPTUM

The ventricular septum is composed of two components: (a) the membranous septum, which is an extremely small (5 mm in diameter in the adult heart) and superior portion wedged between the tricuspid and aortic valves; and (b) the large muscular septum. The membranous septum consists of two portions separated by the septal leaflet of the tricuspid valve: the pars atrioventricularis, where left ventricular to RA shunts occur, and the pars interventricularis, where VSDs are located. The muscular septum consists of three portions: the inlet portion, which is inferior to the membranous septum and is between the atrioventricular valves; the trabecular portion, which extends from the membranous septum to the apex; and the conal (or outlet or infundibular) septum, immediately below the pulmonary valve.

Many VSDs typically occur along embryologic fusion lines (e.g., a perimembranous outlet VSD is along the fusion line between the membranous and conal septa). VSDs within the membranous septum can be assessed in the parasternal long and short-axes, apical five-chamber, and subcostal views. In the basal short-axis view where the subpulmonary and subaortic regions can be imaged simultaneously, it can be determined whether an outlet VSD is below the crista supraventricularis (infracristal outlet VSD) or above the crista (supracristal outlet VSD, also known as subpulmonic or doubly committed VSDs). The membranous septum is seen well in the parasternal long-axis sweep from the standard view toward the tricuspid valve. In the apical view, the transducer should be swept anteriorly so that the left ventricular outflow tract and aorta are visualized. VSDs within the conal septum are assessed in the parasternal long axis sweeping left toward the pulmonary valve, in the basal short-axis, and in the subcostal coronal and sagittal views. The trabecular septum is so large that defects within it need to be localized preferably describing their position in two orthogonal planes and in relation to nearby landmarks. One classification system assigns the VSD as anterior, midmuscular, apical, or posterior. Anterior trabecular VSDs can be missed if the echocardiographer is not interrogating consciously for them. Perhaps the best view is the parasternal long-axis view sweeping to the left. The midmuscular VSDs can be seen in the standard parasternal long and short-axes views and apical four-chamber views. VSDs in the posterior trabecular septum are visualized best in the parasternal short-axis view or in the apical view swept posteriorly. Apical trabecular defects are best seen in the apical four-chamber view inferior to the moderator band. Inlet VSDs are best visualized in the short axis sweeping inferiorly toward the atrioventricular valves and in the standard apical four-chamber view at the level of the atrioventricular valves. These are distinguished from atrioventricular septal defects by close echocardiographic inspection of the hinge points of the atrioventricular valve annuli, which remain normal (i.e., mitral hinge point slightly superior to that of the tricuspid valve) with an inlet VSD and at identical heights with an atrioventricular septal defect.

LEFT VENTRICLE

The size of the left ventricle, which is particularly important in evaluating atrioventricular septal defects and variants of hypoplastic left heart with relative left-sided hypoplasia, is

investigated in the apical four-chamber view. The left ventricular outflow tract, which is important to visualize for membranous and subvalvar stenosis, is seen by a slight anterior tilt of the transducer. Equally valuable for the visualization of the subaortic region is the parasternal long-axis view in which the left ventricular outflow tract is at a slightly shallower depth, improving imaging, or the subcostal coronal view. Trabeculations, the diagnostic feature of left ventricular noncompaction, are best seen at the cardiac apex or lateral wall from a true apical four-chamber view with the apex clearly visible in the sector and with careful, deliberate sweeps in the parasternal short axis from the mitral valve annulus inferiorly to the cardiac apex. It is from this and the parasternal short-axis view that the echocardiographer can assess whether trabeculations are deep and/or extensive enough to meet diagnostic criteria for left ventricular noncompaction (31,32). Others have suggested that a diagnostic ratio for left ventricular noncompaction has little if any pathoanatomical basis. These authors suggest that the mere presence of trabeculations indicate noncompaction (33,34).

Conal Morphology

The conus (or infundibulum) is the cavitory space formed by the muscular segment of the heart that connects the ventricles with the great arteries and separates the atrioventricular and semilunar valves. Abnormalities in conal development consist of variations in the presence, length, and diameters of the subpulmonary and subaortic conus. These variations can lead to (or be associated with) complex malformations, such as tetralogy of Fallot, interrupted aortic arch, transposition of the great vessels, and double-outlet right ventricle.

SUBPULMONIC

In the normal heart, the conus is the nearly vertical tubular outflow portion of the right ventricle, which is separated from the nearly horizontal right ventricular inflow portion by distinct muscle bands. These muscle bands form a near-circular rim formed by the parietal band anteriorly, the crista supraventricularis posteriorly, and the septal band medially and prohibit pulmonary valve to atrioventricular valve continuity. The subpulmonary conus is best identified in the subcostal views. Leftward anterior deviation of the conal septum leading to a narrowed conus and subvalvar pulmonary stenosis in tetralogy of Fallot is evident in these views. Posterior deviation of the conal septum with VSD results in left ventricular outflow tract obstruction and is associated with interrupted aortic arch. The conal septum in this lesion is best assessed from the parasternal long-axis view.

SUBAORTIC

Persistence of the subaortic conus and involution of the subpulmonic conus is the usual conal relationship in D- (or L-) transposition of the great vessels (35). The subaortic conus is evident on the subcostal coronal and sagittal views. Persistence of subaortic conus prohibits continuity of the aortic valve to either atrioventricular valve. Involution of the subpulmonary conus allows continuity between the pulmonary valve and both atrioventricular valves in transposition of the great vessels. An extremely unusual variant of conal morphology is a subpulmonic conus in the setting of D-transposition of the great vessels.

BILATERAL

Bilateral persistence of the subarterial conus usually results in double-outlet right ventricle. Because the main goal of surgical correction of double outlet right ventricle is to connect the aorta with the morphologic left ventricle through the VSD, it is important to determine the conal relationships with each other and with the great vessels. In double-outlet right ventricle, the relationship of the great arteries with each other is

an inaccurate method by which to determine the infundibular relationships. Particularly important is to determine which conus has the interventricular septum as one of its walls, to localize the VSD with respect to the conus, and to determine the connection of the conus to the aorta.

When two conuses are present, their relationship may be classified as either (a) anterior/posterior or (b) side-by-side (36). With anterior/posterior conal relationship, the VSD is usually subaortic; with the side-by-side relationship, the defect is usually subpulmonic. The conal relationship can be determined by subcostal coronal and sagittal imaging with anterior/posterior and left/right sweeping, respectively. With an anterior/posterior conal relationship, the outlet septum inserts anteriorly separating the anterior conus from most of the interventricular septum and, thus, the VSD. With a side-by-side conal relationship, the outlet septum inserts near the crux of the heart separating the lateral conus from the interventricular septum and VSD.

Bilateral conus also can be associated with D-transposition of the great vessels with VSD, a more anterior and superior location of the pulmonary root than in patients with a subaortic conus only, and discontinuity between the pulmonary and mitral valves (as well as between the aortic and tricuspid valves). L-Transposition of the great vessels also can be associated, although rarely, with bilateral conus evident in the subcostal views.

ABSENT

A rare type of D-transposition can exist in the context of bilaterally deficient subarterial conus (37). This results in an unusual heart in which D-transposition of the great vessels exists with a doubly committed VSD and a posterior aorta. These relationships can be identified by parasternal and subcostal coronal and sagittal imaging (Fig. 8.25).

Ventriculoarterial Connection

TYPE

If the aorta arises from the left ventricle and the pulmonary artery arises from the right ventricle, the relationship is concordant. When the aorta arises from the right ventricle and the pulmonary artery from the left ventricle, the relationship is discordant. The third type of ventriculoarterial connection is double outlet, almost always from the right ventricle. The ventricular origins of aorta and pulmonary artery are evident on the parasternal long-axis view, sweeping the transducer inferiorly from the basal short-axis view, the apical five-chamber view, and the subcostal coronal and sagittal views. A great vessel should be related to a ventricle by at least 50% of its dimension to be considered committed to it. Determining the extent of commitment of a great vessel to the right ventricle is best performed in the parasternal long- and short-axis view sweeps, the apical five-chamber view, and the subcostal coronal and sagittal views. The final type of ventriculoarterial connection is single outlet (truncus arteriosus). This entity can be diagnosed in the parasternal long axis, where a single trunk with pulmonary arteries arising from it can be seen. The basal short-axis view is notable for absence of a pulmonary valve; the pulmonary artery branches arising from the trunk also can be seen in this view. The subcostal coronal and sagittal views are usually diagnostic for this entity.

Great Vessels

RELATIONSHIP

The aorta courses superiorly toward the thoracic inlet before coursing posteriorly, gives rise to strap vessels as it courses posteriorly, and has coronary arteries arising from its root. The pulmonary artery courses posteriorly almost immediately after it arises from the heart and bifurcates shortly after its origin. The most helpful views for identifying the great vessels

Figure 8.25. Parasternal long-axis images of a patient with bilaterally absent conus resulting in transposition of the great vessels (i.e., ventriculoarterial discordance) with not only mitral-pulmonic continuity (arrowhead in standard parasternal long-axis view (A) but also tricuspid-aortic continuity (arrowhead in parasternal long-axis view swept right and inferiorly (B)). A, anterior; AoV, aortic valve; I, inferior; LV, left ventricle; MV, mitral valve; PV, pulmonary valve; RV, right ventricle; TV, tricuspid valve.

Figure 8.26. Parasternal short-axis images demonstrating different relationships between the great vessels. **A:** An echocardiogram from an infant demonstrates the identifying features of a pulmonary artery with its bifurcation into right and left pulmonary arteries (RPA, LPA). This view is called the “3 finger view” as it also demonstrates the PDA. The great vessels are normally related with the pulmonary valve (PV) lying anterior and left of the aorta. **B:** In a patient with D-transposition of the great vessels, both semilunar valves are in cross section in the parasternal short-axis view. The aorta (Ao) is identified as the anterior and slightly rightward vessel. The main pulmonary artery (PA) lies posterior to the Ao and bifurcates into RPA and LPA. A, anterior; R, right; RV, right ventricle.

are the parasternal short-axis view at the base and even more superiorly, the suprasternal notch long- and short-axis views, and the subcostal coronal and sagittal views (Fig. 8.26).

Situs solitus of the great vessels describes the normal relative position of the aortic annulus located rightward and posterior to the pulmonary annulus. This relationship is best seen in the parasternal short-axis view, but it is also obvious in the parasternal long-axis sweeps and the subcostal coronal and sagittal views.

Situs inversus of the great vessels describes the relative position of the aortic annulus located leftward and posterior to the pulmonary valve annulus in mirror image dextrocardia. Note that the term “inversus” in this context does not signify transposition. It is merely the designation given to normally related great vessels in a mirror-image relationship (i.e., the aorta continues to arise from the left ventricle and the pulmonary artery from the right ventricle). This relationship is evident in a right parasternal short-axis view and in the subcostal coronal and sagittal sweeps.

Transposition of the great vessels is diagnosed when there is a discordant ventriculoarterial relationship. By definition, then, it is impossible to diagnose double-outlet right ventricle with transposition. Instead, this is referred to as double-outlet right ventricle with **malposition** of the great vessels. Transposition of the great vessels can exist with the aorta right and

anterior (D), left and anterior (L), and directly anterior (A) to the pulmonary artery. In addition, the aorta may exist side-by-side or even posterior to the pulmonary artery. These relationships are best diagnosed in the basal short-axis and subcostal coronal and sagittal views.

MAIN AND BRANCH PULMONARY ARTERIES

The main and branch pulmonary arteries are best seen in the basal (and more superior) short-axis and subcostal coronal and sagittal views. In addition, the right pulmonary artery is best seen in the suprasternal short-axis view. The left pulmonary artery usually can be seen when sweeping the standard suprasternal long-axis view to the left.

Pulmonary valve stenosis is evident in the parasternal basal short-axis view. Frequently, continued clockwise rotation of the transducer can yield an *en face* view of the pulmonary valve. Supravalvar pulmonary stenosis is best visualized in this view. Aortopulmonary window is usually evident on the parasternal short-axis view and careful, deliberate sweeps between the aorta and main pulmonary artery in the subcostal coronal and sagittal views.

AORTA AND BRANCH VESSELS

The aorta, which lies more posterior in the center of the heart, can be visualized in many different views, including the parasternal long- and short-axis views, the apical five-chamber view, the subcostal views, and the suprasternal notch views. The aortic arch is best seen in the subcostal oblique view and the suprasternal notch views.

Valve morphology in aortic stenosis can be understood by examining the parasternal views. The short-axis views allow determination of dysplasia and number of leaflets. Supravalvar stenosis, root dilation, and sinotubular effacement are best measured in the parasternal long-axis view.

The side of the aortic arch (important in tetralogy of Fallot, truncus arteriosus, hypoplastic left heart, vascular rings, and before tracheoesophageal fistula repair) is diagnosed by sweeping the transducer in the suprasternal long-axis view and noting the relationship of the arch to the trachea, the rings of which resemble a stack of coins. Equally important is sweeping the transducer in the suprasternal notch short-axis view from the origin of the aorta superiorly toward the arch and branch vessels and then back inferiorly and posteriorly following the descending aorta. Using this view, the transducer should also be swept superiorly to follow the course of each branch vessel arising from the arch. In a normal, left-sided aortic arch, the first branch vessel is a right brachiocephalic artery that can be shown to bifurcate into right subclavian and carotid arteries (Fig. 8.27). In a right-sided aortic arch, the first branch vessel is usually a left brachiocephalic artery, which usually bifurcates into a left subclavian and carotid arteries. In either case, the first branch vessel should be followed to its bifurcation. If no bifurcation is present, anomalous origin of the ipsilateral subclavian artery should be suspected. Likewise, superior sweeping from the origin of each of the other strap vessels upstream should be performed deliberately to completely delineate the strap vessel anatomy.

Arch hypoplasia, coarctation, and interruption are best diagnosed from the suprasternal long- and short-axis views. The proximal (the segment between brachiocephalic and common carotid artery origins) and distal (the segment between common carotid artery and subclavian artery origins) transverse arch should be imaged and measured.

Aortopulmonary collateral vessels (important in tetralogy of Fallot and single ventricle/Fontan physiology) are best seen in the suprasternal notch long- and short-axis views. The subcostal oblique view of the descending aorta also allows identification of these vessels.

Coronary Arteries

The coronary arteries are best seen in the parasternal short-axis views. The coronary arteries can also be seen in the apical four-chamber view as they course in the atrioventricular grooves. The midportion of the right coronary artery is seen in the subcostal coronal view. Frequently, the origin of the left coronary artery and the left anterior descending coronary artery are seen in the subcostal coronal view or a leftward sweep from the standard parasternal long-axis view. The posterior descending coronary artery is more difficult to visualize but investigators have had success in imaging it adjacent to the cross section of the coronary sinus from an apical two-chamber view (38).

Anomalous coronary artery origins and courses are important to delineate in transposition of the great vessels, tetralogy of Fallot, anomalous origin of the left (or more rarely, the right) coronary artery from the pulmonary artery, dilated cardiomyopathy, and exertional syncope and are seen in the parasternal short axis. If 2-D imaging in the short-axis view shows isolated dilation of a proximal coronary artery, a coronary artery fistula or anomalous origin of a coronary artery should

Figure 8.27. Suprasternal notch short-axis views in a patient with left aortic arch (A) and a second patient with right aortic arch (B). In each view, the transducer is swept superiorly to demonstrate the bifurcation of the brachiocephalic artery. In the patient with a left aortic arch, the first strap vessel arising from the aortic arch is the brachiocephalic artery which bifurcates toward the right into right subclavian (RSCA) and right common carotid arteries (RCCA), indicating a left aortic arch. In the second patient with a right aortic arch (B), the first strap vessel is a left brachiocephalic artery, and it bifurcates to the left into the left subclavian (LSCA) and left common carotid (LCCA) arteries, indicating a right aortic arch. Color Doppler can be helpful in tracking these arteries distally to determine their branching patterns as shown by the color Doppler panel in B. R, right; S, superior.

be suspected. The entire extent of the coronary artery must be interrogated for fistulous communications from all imaging planes. The main and branch pulmonary arteries should be carefully imaged for an anomalously arising coronary artery. Simultaneous use of color Doppler is extremely helpful when investigating for coronary artery fistulae or anomalous origin of a coronary artery. Coronary cameral sinusoids, seen within high pressure ventricles such as the right ventricle in pulmonary atresia with intact ventricular septum, are best visualized in the apical four-chamber view with simultaneous use of color Doppler. Evaluation of the coronary arteries during and following Kawasaki disease for aneurysms and stenoses should be performed in all the aforementioned imaging planes so that almost the entire extent of the coronary artery is interrogated.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

In 1991, Ritter (39) reported initial experience of biplane transesophageal echocardiography (TEE) to evaluate congenital heart disease in patients as small as 2.4 kg without complications,

and it later became clear that intraoperative echocardiography allowed immediate revision of initial repair and improved patient outcome (40). In addition, TEE has become standard for guidance of defect-closure devices during interventional catheterization procedures (41), guidance of balloon atrial septostomy, and evaluation for thrombi (42).

Approach

The probe should be inspected carefully for any defects before it is inserted into the oropharynx. Probe size should be chosen on the basis of the patient's weight. Generally, current pediatric size TEE probes can be safely used in patients as small as 3.5 kg; recently, use of newer "micro-TEE" probes have been reported in infants as small as 1.7 kg (43). Esophageal intubation can be enhanced with the neck slightly flexed and the patient in a slight left lateral decubitus position. Under no circumstances should the probe be forced into the posterior pharynx; sometimes direct visualization with a laryngoscope for difficult intubations is necessary.

Probe manipulation consists of the transesophageal equivalents of transthoracic sweeps: withdrawing or advancing the transducer superiorly and inferiorly within the esophagus, rotating the transducer left and right, ante- or retroflexing the transducer, or flexing left or right (Fig. 8.28). In addition, the imaging plane can be mechanically adjusted from 0 to 180 degrees in the case of multiplane TEE probes (Fig. 8.29), or from horizontal to vertical imaging planes in the case of biplane imaging (Fig. 8.30). Currently, multiplanar TEE probes are available widely in pediatric sizes, so increasingly, multiplane (rather than biplane) imaging is performed.

The examination should proceed in a segmental manner with identification of the systemic venous return moving the transducer superiorly and inferiorly in the esophagus in the longitudinal and transverse views. The atrial septum should be examined in these same views. The tricuspid valve is best visualized in the transverse four-chamber view and the longitudinal plane with rightward rotation. The interventricular septum is visualized in the transverse four-chamber view, sweeping the longitudinal view from left to right and in the transgastric views. The right ventricular outflow tract and pulmonary valve are seen in a superior transverse view, in the longitudinal view swept leftward from the aorta, and in the longitudinal gastric view. On multiplane imaging, the tricuspid valve, right ventricular outflow tract, pulmonary valve, and membranous/outlet interventricular septum can also be imaged in a 60- to 70-degree plane (Fig. 8.31). Pulmonary veins are best seen in the transverse plane by sweeping right and left. The mitral valve is investigated from the transverse four-chamber view and the longitudinal plane with a far leftward sweep. The left ventricular outflow tract and the aorta are evaluated in a slightly superior sweep from the transverse four-chamber view and in the longitudinal view between the SVC and the pulmonary artery. On multiplane imaging, the left ventricular outflow tract, aorta, and outlet interventricular septum are also imaged well at an imaging angle of approximately 120 degrees (Fig. 8.32).

Complications from TEE are rare; however, there are reports of upper-airway obstruction secondary to esophageal hematoma (44), compression of an aberrant right subclavian artery (45), accidental endotracheal tube extubation, and esophageal burns and tears resulting from defective or improperly maintained probes. In a large review of 1,650 transesophageal studies in the pediatric population (46), Stevenson reported an approximately 3% incidence of complications, most of which were related to airway complications (e.g., airway occlusion or displacement of the endotracheal tube) in small infants.

Figure 8.28. Terminology used to describe the various transesophageal probe manipulations that can be employed during imaging studies. (Reprinted from Shanewise JS, et al. ASE/SCA Guidelines for Performing a Comprehensive Intraoperative Multiplane Transesophageal Echocardiography Examination: Recommendations of the American Society of Echocardiography and the Society of Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography. *J Am Soc Echocardiogr* 1999;12:884-900, with permission from Elsevier.)

Intraoperative Transesophageal Echocardiography

The value of intraoperative TEE is in evaluating residual problems relating to ventricular outflow tract obstruction, semilunar valve insufficiency, septal defects, atrioventricular valve insufficiency and stenosis, and ventricular function and wall-motion abnormalities. Stevenson et al. (47) reported that reoperation occurred in 7.5% of cases as a result of residual findings on intraoperative TEE. Ungerleider et al. (40) showed a similarly low rate of reoperation, but also demonstrated a significant impact on length of stay and hospital costs for patients undergoing immediate reoperation because of intraoperative echocardiographic findings. In addition, the knowledge that a repair is satisfactory helps guide bypass weaning and immediate postoperative care. Although intraoperative imaging can confirm adequate surgical repair/palliation, findings can evolve postoperatively due to changing hemodynamics, loading conditions, or other factors, which may make repeat imaging necessary or advisable. For example, the degree of valvar regurgitation seen on pre-discharge echocardiography is often different than on intraoperative transesophageal study in patients following repair of atrioventricular septal defects (48,49) and atrioventricular valve regurgitation (50).

Figure 8.29. There are multiple imaging planes available during multiplane TEE based on level of the transducer and rotational angle. AV, aortic valve; LAX, long axis; ME, midesophagus; RV, right ventricle; SAX, shortaxis; TG, transgastric; UE, upper esophagus. (Reprinted from Shanewise JS, et al. Guidance of Transcatheter Device Closure

TEE has proven value in guiding interventional catheterization procedures; this is discussed in detail in Chapter 13.

Evaluation for Thrombi and Complications of Endocarditis

Consideration of performing TEE should be given when there is suspicion of thrombi (i.e., because of neurologic changes, dysrhythmias, spontaneous contrast on the transthoracic echocardiogram). Patients with the Fontan procedure, particularly those with an atriopulmonary anastomosis, are at high risk for developing thrombi in the RA, IVC, or pulmonary artery (51) (Fig. 8.33).

TEE may have utility in the evaluation of suspected infective endocarditis in children, but may not be necessary when transthoracic imaging is adequate (52,53). Although TEE has been shown to be significantly more sensitive than transthoracic echo in diagnosing valvular vegetations and abscesses in adults with suspected endocarditis (54–56), higher quality acoustic windows in the pediatric population in general may negate the improvements in diagnostic sensitivity seen with use of TEE in adults (52,53). Moreover, the use of TEE in children is generally performed under conditions of endotracheal intubation and deep sedation/anesthesia, making the performance of TEE more invasive in this population. Therefore, TEE should be performed in any patient with suspected endocarditis, in whom the transthoracic study is negative or inconclusive due to technical inadequacies. Alternatively, in the patient with confirmed endocarditis, TEE may be useful in

more fully delineating the cardiac sequelae, such as perivalvar abscess and extent of vegetations (52).

STRESS ECHOCARDIOGRAPHY

Stress echocardiography is a valuable adjunct to the standard examination in two general instances. First, if there is a

concern in a patient with coronary artery disease (e.g., due to Kawasaki Disease, cardiac transplant vasculopathy, arterial switch operation, et al.), stress echocardiography may be helpful. In these circumstances, stress echocardiography is used to determine the physiologic significance of the anatomic abnormalities. A stressor is administered (e.g., exercise or pharmacologic) with the intention of increasing myocardial oxygen demand. In normal coronary arteries, blood flow increases to

Figure 8.30. There are two basic imaging planes used in pediatric TEE: the horizontal imaging plane (A) and the vertical imaging plane (B). Omniplane probes can image at planes intermediate between these two. Imaging can be performed in three basic esophageal positions: the midesophagus, the upper esophagus at the base of the heart, and transgastrically. Horizontal-plane imaging in the midesophagus provides the four-chamber view, coronary sinus view, and pulmonary vein view. Horizontal imaging in the higher esophagus provides views of the base of the heart, including the aorta, coronary arteries, pulmonary valve, branch pulmonary arteries, pulmonary veins, and superior vena cava (SVC). Horizontal imaging in the transgastric view yields a short-axis view of the ventricles. Vertical imaging in the midesophagus provides views of the left ventricular outflow tract and the mitral valve. Vertical imaging in the higher esophagus provides views of the right ventricular outflow tract, main pulmonary artery, branch pulmonary arteries, left ventricular outflow tract, aorta, SVC, and atrial septum. Transgastric vertical plane imaging provides images of the left ventricular and right ventricular outflow tracts. A, aorta; AO, aorta; AV, aortic valve; CS, coronary sinus; FO, foramen ovale; IVC, inferior vena cava; LA, left atrium; LAA, left atrial appendage; LCA, left carotid artery; LLPV, left lower pulmonary valve; LPA, left pulmonary artery; LPV, left pulmonary valve; LUPV, left upper pulmonary valve; LV, left ventricle; MPA, main pulmonary artery; PV, pulmonary valve; RA, right atrium; RAA, right atrial appendage; RCA, right coronary artery; RPA, right pulmonary artery; RUPV, right upper pulmonary valve; RV, right ventricle; SVC, superior vena cava.

Figure 8.30. (Continued)

meet this demand. However, if in a diseased coronary artery, flow is compromised; ischemia is induced to the myocardial segment supplied by that coronary artery which is manifest on the echocardiogram by altered wall motion of that segment.

The second general use of stress echocardiography is evaluating a patient's hemodynamics in a setting other than the resting state. Children are rarely sedentary. Yet, echocardiographic examinations are largely performed when the child is in a resting, supine state—a condition that the child is actually experiencing for only brief moments during the day. These resting examinations shed little light on the child's typically more active physiology which, ironically, becomes apparent only after the patient leaves the laboratory. An echocardiographic assessment with the addition of a stressing agent provides greater insight into the hemodynamics present during the active state typical of children. One simple approach is the force-frequency relationship—increasing frequency of contraction induced by cardiac pacing (57) results in increased contractile force generation (as measured by ejection phase indices or by wall stress relations) with a maximal force (F_{\max}) at a

stimulus frequency of approximately 175 beats/min (Treppe phenomenon). Thereafter, the response becomes inverted (increased frequency results in decreased force). In the chronically failing heart due, for example, to dilated cardiomyopathy, mitral insufficiency, or diabetic cardiomyopathy, F_{\max} is depressed due to decreased activity of the calcium adenosine triphosphatase in the sarcoplasmic reticulum (SERCA-2) (58). Another, similar approach is the assessment of contractile reserve. In chronic heart failure, a rise in circulating catecholamines is accompanied by decreased beta receptor density and downregulation of receptors leading to a poor response to inotropic agents (59). Poor contractile response to exogenous catecholamines, therefore, has prognostic value in identifying the marginal ventricle more likely to require chronic medications, assist devices, and possibly transplant (60) and is associated with overexpression of apoptosis-related proteins (61–63). The magnitude of augmentation of cardiac performance during cardiovascular stress is termed contractile reserve and can be assessed noninvasively using exercise or pharmacologic stress (64–66).

Figure 8.31. Multiplane TEE at midesophagus with imaging angle at approximately 60 degrees. This imaging plane allows demonstration of the aortic valve (Ao) in short axis, as well as the right ventricular (RV) body and outflow tract. The proximal main pulmonary artery (MPA) can also be imaged, as well as the pulmonary valve (open arrow). The tricuspid valve (open arrow) can also be noted. Note the perimembranous ventricular septal defect (asterisk) in this image. ANT, anterior; SUP, superior.

Technical Aspects

In pediatrics, the usual stressors are exercise and dobutamine (67,68). Exercise is the reference standard, and most of the other stressing agents are employed to mimic it. However, exercise has the disadvantages of (a) patient movement and respiration, which impair echocardiographic imaging; and (b) lack of threshold dosing (the entire stress dose is given without the option for early termination). Since imaging is so poor during exercise, echocardiography must be performed

immediately after exercise, necessitating a hurried process to acquire images before the exercise dose dissipates (usually <60 seconds). Dobutamine infusion offers a controlled environment in which dosing can be gradually increased or terminated on the basis of immediate echocardiographic feedback. Imaging is usually excellent because there is no patient movement or deep respirations. The main disadvantage of dobutamine is that it does not duplicate exercise exactly.

For an exercise echocardiogram, imaging is performed in four echocardiographic planes (parasternal long- and short-axis, apical two- and four-chamber views) with the patient in a left lateral decubitus position before, immediately after, and 20 minutes after exercise. For a dobutamine stress echocardiogram, imaging is performed in the same four planes at rest, at each dobutamine dose, at peak heart rate, and 20 to 30 minutes after termination of dobutamine. Dobutamine is given in consecutive doses of 10, 20, 30, 40, and 50 mcg/kg/min. Atropine (0.01 mg/kg) is administered to augment the heart rate, if necessary. The test is terminated if (a) target heart rate (85% of age-related maximal heart rate) is achieved, (b) adverse reactions occur, (c) the electrocardiogram shows abnormalities (e.g., significant ST segment depression or significant dysrhythmia), (d) the patient's rating of perceived exertion is excessive (exercise), or (e) the maximum dose has been given (dobutamine).

Wall Motion Abnormalities

Wall motion abnormalities are the diagnostic feature of a myocardial perfusion deficit during a stress echocardiogram. Detection of a wall motion abnormality is the most difficult part of a stress echocardiogram. It is essential that pediatric cardiologists contemplating the introduction of stress echocardiography into their laboratories receive and maintain adequate training in the interpretation of wall motion from adult cardiologists. In evaluating wall motion, it frequently helps to first examine the overall end-systolic cavity size. If there is little or no change at peak heart rate versus rest, abnormal wall motion is diagnosed and each segment examined in detail to detect specific regional wall motion abnormalities. In addition, an abnormality seen in one view should be verified by examination of the same or adjacent segment in another view.

Diagnosis of pathology based on myocardial wall motion during stress is based on four basic response patterns: normal motion at rest and normal motion during stress indicates normal myocardium; normal motion at rest and abnormal motion during stress indicates ischemic myocardium; abnormal motion at rest and abnormal motion during stress indicates necrotic myocardium; and abnormal motion at rest and normal or biphasic response during stress indicates viable myocardium (hibernating myocardium) (69).

Wall motion scoring systems have been defined by segmenting the left ventricle into 16 or 17 segments and assigning a score of "1" to a segment with normal motion, "2" to a segment that is hypokinetic, "3" to a segment that is akinetic, and "4" to a segment that is dyskinetic. The sum of segment scores divided by the number of visualized segments is the wall motion score index (70).

Wall motion scoring systems are based on subjective assessment. Strain imaging and 3-D echocardiography have also been used to enhance detection of, and to quantify, wall motion abnormalities during stress echocardiography in adults but experience is lacking in children (71,72).

Whereas stress echocardiography administered to unmask occult coronary artery disease requires a large stressing dose to maximize myocardial oxygen consumption, administration of stress for assessment of contractile reserve requires far less but nevertheless still substantial dosing (dobutamine

Figure 8.32. Multiplane TEE at midesophagus with imaging angle at approximately 120 degrees. The mitral valve anterior leaflet (open arrow), left ventricle (LV), outflow tract, and aortic valve (Ao) can be demonstrated in this plane. Portions of the right ventricular (RV) outflow tract, and an outlet ventricular septal defect (asterisk) are also noted. ANT, anterior; SUP, superior.

Figure 8.33. A: Transthoracic apical four-chamber view in an adolescent patient with pulmonary atresia and intact ventricular septum who had previously undergone a classic Fontan procedure with the right atrium (RA) directly anastomosed to the pulmonary artery. The electrocardiogram shows atrial fibrillation/flutter. The patient was being evaluated for the possibility of thrombi before DC cardioversion. This echocardiogram revealed no obvious thrombi. In particular, the RA appeared free of thrombus. B: Transesophageal echocardiogram of the RA in the horizontal plane. There is marked spontaneous contrast indicative of a thrombogenic milieu. In addition, there are two large thrombi on the RA free wall. Further imaging revealed thrombi in the midcavity of the RA and at the inferior vena cava orifice. Transthoracic echocardiography may lead to false-negative results, and TEE is often necessary to evaluate for thrombi, particularly in patients with classic Fontan operation. A, anterior; I, inferior; LA, left atrium; LV, left ventricle; P, posterior; RV, right ventricle.

at ~ 20 mcg/kg/min) (73). Normal responses of left ventricular performance (shortening fraction) and contractility (VCF_d difference) to exercise and dobutamine stress have been established (73,74) (Fig. 8.34). Stress echocardiography can also be used to assess the changing behavior of various cardiac lesions during altered activity levels (Fig. 8.35). For example, the gradients in hypertrophic cardiomyopathy, coarctation, pulmonary or aortic valvar stenoses (75), and the pulmonary artery pressure in patients with suspected pulmonary hypertension can all be evaluated with echocardiography during stress.

THREE-DIMENSIONAL ECHOCARDIOGRAPHY

The goal of the echocardiographic examination is to create and convey a 3-D reconstruction of the heart. Historically, 3-D reconstruction has been a mental process dependent on the ability of the viewer to spatially “render” a 3-D image of the heart using 2-D images. This can clearly be improved on by an actual visual 3-D reconstruction. Three-dimensional images can be produced with any medical imaging technique, but echocardiography is uniquely qualified because images are tomographic, are acquired at a relatively high rate, can be triggered to an appropriate phase of the electrocardiogram, and can be acquired from any angle.

Evolution of current 3-D ultrasound systems progressed from static to dynamic, and ultimately, to real-time 3-D imaging. Static 3-D images were initially obtained from a single volume of “voxels”—a volume of pixels—by sweeping the ultrasound transducer through the area of interest. Although this can be achieved by sweeping the ultrasound probe through the area of interest by linear, fan-like or rotational sweeps, this technique was ultimately supplanted by rotational acquisition (76,77). Dynamic 3-D imaging is also possible, but portrayal of the heart in motion was dependent on reconstruction

algorithms that were in turn dependent on 2-D image quality, and were often deemed impractical due to the long and tedious nature of data acquisition and data analysis. The current state-of-the-art in 3-D imaging is represented by real-time 3-D imaging. Several recently developed ultrasound systems (78) feature matrix array transducers, which allow acquisition of high-quality, pyramidal image volumes (Fig. 8.36). Advances in 3-D ultrasound processing and faster computing times has currently made “real-time” 3-D imaging possible (79), which is likely to lead to increasing use in the future. Recently, development of higher frequency, matrix array TEE probes has resulted in excellent 3-D image quality in real time (80). Currently, 3-D echocardiography has the potential to add to what 2-D imaging can offer in pediatric heart disease in several areas: (a) anatomic imaging in the setting of structural heart disease, (b) quantitative evaluation of chamber volumes and function, and (c) guidance during cardiac interventional procedures.

Anatomic Imaging in Structural Heart Disease

Three-dimensional echocardiographic reconstruction has the potential to provide unique information regarding cardiac anatomy. Recent reports have demonstrated that 3-D imaging of the atrioventricular valves may augment clinicians’ understanding of the mechanisms of atrioventricular valve regurgitation during valve repair in atrioventricular septal defects (81–83) (Fig. 8.37), and in a variety of congenital heart lesions, including the tricuspid valve in hypoplastic left heart syndrome (83) and in Ebstein anomaly (84). Three-dimensional assessment of aortic valve area in the setting of valvar aortic stenosis has also been described (85,86). Assessment of both native and prosthetic mitral valve abnormalities has been shown to be both feasible and accurate using 3-D techniques (80,87).

Figure 8.34. Normal responses to VCF difference, a quantitative measure of left ventricular contractility, in children during exercise (A) and during dobutamine stress (B). (Reprinted from Kimball TR, Mays WA, Khoury PR, et al. Echocardiography determination of left ventricular preload, afterload, and contractility during and after exercise. *J Pediatr* 1993;122:S92-S93, with permission from Elsevier. Reprinted from Michelfelder EC, Witt SA, Khoury P, et al. Moderate-dose dobutamine maximizes left ventricular contractile response during dobutamine stress echocardiography in children. *J Am Soc Echocardiogr* 2003;16:144, with permission from Elsevier.)

Three-dimensional echocardiography can also add incremental imaging data in the setting of both ASD and VSD (88,89). With 3-D echocardiography, anatomy can be viewed from unique perspectives, for example, that of the surgeon (90) (Fig. 8.38). In addition, particularly complex anatomy may be better visualized (91). This may be specifically useful, for example, in determining the relation of the VSD to the great vessels in double-outlet right ventricle.

Quantitation of Cardiac Chamber Volumes and Function

From the quantitative standpoint, it is now possible to evaluate cardiac volumes by real-time 3-D echocardiography. Reliable quantitation of both left atrial (92,93) and

left ventricular volumes and left ventricular ejection fraction (94) is possible, and is comparable to values obtained utilizing cardiac magnetic resonance imaging techniques. Research also indicates that right ventricular volumes can be measured accurately in the pediatric population with a variety of congenital heart lesions (95,96). This information may be helpful in evaluating right ventricular size in patients with relative right ventricular hypoplasia (e.g., in pulmonary atresia with intact ventricular septum) and evaluating right ventricular function in the setting of postoperative tetralogy of Fallot or in systemic right ventricles (e.g., hypoplastic left heart syndrome or transposition of the great arteries following atrial switch procedure). Altmann et al. (97) have also demonstrated that 3-D echocardiographic measurements of single ventricular volume and mass are also accurate and suggest this technique for assessing cardiovascular status in this

Figure 8.35. Mitral valve Doppler tracings from an apical four-chamber view in a 16-year-old male with a prosthetic mitral valve at baseline (A) and at peak exercise (B). The mean mitral valve gradient at baseline is 10.5 mm Hg. With exercise, the mean gradient increases to 47 mm Hg.

Figure 8.36. With a matrix array transducer, “full volume” 3-D images can be obtained. Thousands of imaging elements in the transducer head allows acquisition of “voxels” in either real time at a smaller (30 to 50 degrees) sector angle, or by electrocardiographically gated acquisition of smaller volume sectors that are integrated into a volume with a larger (90 degrees) sector angle.

Figure 8.37. Three-dimensional imaging of an atrioventricular septal defect. Three-dimensional image processing of this apical view has removed the right atrial and right ventricular free walls and allows visualization of the right atrial and right ventricular septal surface, including imaging of the primum atrial septal defect (*open arrow*) and inlet ventricular septal defect (*asterisk*). The superior (SBL) and inferior (IBL) bridging leaflets of the common atrioventricular valve can also be seen. A, anterior; I, inferior; P, posterior; S, superior. (Image courtesy of Dr. Girish Shirali, Medical University of South Carolina.)

Figure 8.38. Three-dimensional, “surgeon’s view” of the tricuspid valve. The anterior (*white arrow*) and posterior (*asterisk*) tricuspid valve leaflets can be identified; the septal leaflet is open but oriented into the plane of the image. The floor of the RA and coronary sinus ostium (*grey arrow*) is also demonstrated. ANT, anterior.

high-risk population. Other emerging quantitative modalities in 3-D echocardiography include 3-D assessment of intra-ventricular regional function and dyssynchrony (98–100), although these techniques are not yet widely used, particularly in the pediatric population.

3-D Guidance of Cardiac Interventional Procedures

Three-dimensional echocardiography is gaining increasing use in both the intraoperative setting and during catheter-based interventional procedures.

ECHOCARDIOGRAPHIC EVALUATION OF INTERVENTIONAL PROCEDURES

As the field of transcatheter cardiac intervention has expanded the availability of devices and interventions, echocardiographic techniques to evaluate and monitor these procedures have also necessarily expanded. In this section, we review common techniques in echocardiographic evaluation of device deployment in the catheterization laboratory. Following an early experience in transcatheter intervention using only angiography, TEE quickly became established as a vital imaging tool during these procedures (101), particularly during device closure of atrial and ventricular septal (41) defects. As new septal occluder devices continued to be developed, TEE continued to demonstrate its utility in guiding device deployment and assessing outcomes for both atrial (102–104) and ventricular septal (105,106) occluder devices.

Subsequently, intracardiac echocardiography (ICE) was reported. ICE employs a small (10 F, 3.2 mm) catheter with a high frequency ultrasound transducer in its tip. These transducers could image in a longitudinal plane with a sector angle of 90 degrees, and a depth of penetration to 12 cm. ICE was also reported to be useful and effective in demonstrating pertinent anatomy and monitoring device deployment, particularly during device occlusion of ASDs and patent foramina ovale (107–110). A potential advantage of ICE imaging is that it does not require general anesthesia or intubation, as is often necessary in children undergoing TEE (107).

Three-dimensional echocardiography has also been described as a potentially useful modality in the pre- and postprocedure evaluation of the atrial septum before and after device occlusion of ASD (111). More recently, real-time 3-D TEE has proven useful for determining atrial septal anatomy, defect size, rim dimensions, and device position (Fig. 8.39) in the interventional catheterization laboratory (112,113), and may actually reduce fluoroscopy time during these procedures (112).

Regardless of the echocardiographic modality being employed, the goals of echocardiographic evaluation before, during, and after device deployment include: (a) pre-procedure assessment of pertinent anatomy; (b) monitoring during intervention and device deployment; and (c) anatomic assessment after device deployment.

Atrial Septal Defect

In general, only secundum ASDs or patent foramen ovale are amenable to device occlusion. Care should be taken to inspect the defect for size and location. Measurement of the defect size on 2-D imaging should be performed. Assessment of tissue rims around the defect is important in determining the ability of the device to anchor around the defect margins (Fig. 8.40A). The position of the ASD relative to other important cardiac structures, for example, right pulmonary veins, mitral valve, aorta,

Figure 8.39. Real-time, three-dimensional transesophageal echocardiogram after deployment of an atrial septal defect occluder device. The left atrial disc of the device can be seen centrally along the left atrial aspect of the interventricular septum (arrow). (Image courtesy of Phillips Medical Co., Bothell, WA.)

and coronary sinus should be noted. During the procedure, the position of sheaths and guidewires should be documented and communicated to the interventionalist. As most ASD occluder devices now consist of a dual “disk” design, deployment of the left atrial disk in the LA should be confirmed, then proper seating of the disc upon the atrial septum is noted. Full deployment of the right atrial disc and assessment of the entire device relative to its position on the atrial septum, presence/absence of residual shunting, and potential impingement on adjacent structures should be evaluated prior to release of the device. Findings should be reevaluated following release of the device from its guidewire (Fig. 8.40B). It is important that unique characteristics of each device be known and understood during the imaging evaluation (102,103,114–116).

Ventricular Septal Defect

Specific devices for closure of perimembranous (105,117) and muscular (106,118) VSDs have been reported. Care should be taken to inspect the defect for size and location. Measurement of the defect size on 2-D imaging should be performed. Assessment of tissue rims around the defect are important in determining the ability of the device to anchor around the defect margins, and to assess the potential of the device to impinge on other important cardiac structures, for example, atrioventricular valve and chordal apparatus. During the procedure, the position of sheaths and guidewires should be documented and communicated to the interventionalist. Deployment of the device into the left ventricle should be confirmed (Fig. 8.41A), and then proper seating of the disc upon the ventricular septum noted (Fig. 8.41B). Full deployment of the device and assessment of the entire device relative to presence/absence of residual shunting, and potential impingement on adjacent structures should be evaluated prior to release of the device. Findings should be reevaluated following release of the device from its guidewire to rule out device embolization (Fig. 8.41C).

Patent Ductus Arteriosus

Transcatheter therapy for PDA most commonly consists of either coil occlusion with Gianturco coils (119,120)

Figure 8.40. Transesophageal imaging during device occlusion of a secundum atrial septal defect (ASD). In panel A, the ASD device is seen straddling the ASD. Rim tissue (*dotted lines*) can be seen between both left atrial (LA) and right atrial (RA) discs. The device has not been released from the guidewire (*white arrow*). In panel B, the device has been fully deployed, and now sits flush against the atrial septum. ANT, anterior; Ao, aorta; LT, left; RT, right; RV, right ventricle; SUP, superior.

or device occlusion, for example, the Amplatzer ductal occluder (119,121,122). Most frequently echocardiography is utilized to assess preprocedure ductal size and morphology, and to evaluate residual shunting postdevice placement.

In addition to assessing residual ductal level shunting, it is important to screen for evidence of device impingement on adjacent vessels, particularly the proximal left pulmonary artery (121).

Figure 8.41. Transesophageal imaging during device occlusion of a posterior muscular ventricular septal defect (VSD). In panel A, the guidewire (*white arrow*) is across the VSD (*open arrow*) and the left ventricular disc has been deployed within the left ventricle (LV). In panel B, the LV disc (*white arrow*) has been positioned against the LV septal surface. In panel C, the device has been released, and both right ventricular (RV) and LV discs can be seen straddling the VSD (*arrows*). ANT, anterior.

CONTRAST ECHOCARDIOGRAPHY

Contrast echocardiography involves administration of one of two distinct contrast agents—agitated saline or commercially available transpulmonary contrast. Although both are administered through an intravenous line, each has a distinct purpose and use.

Agitated Saline Contrast Echocardiography

Principle

Agitation of saline produces microbubbles of gas (10 to 100 μ in diameter) which pass through the circulation until they are filtered and absorbed by transit into a capillary bed. With a systemic intravenous injection, therefore, the microbubble “cloud” will follow the downstream flow of blood, pass into the large systemic veins, and enter the right-sided cardiac structures. In the absence of right-to-left shunts, the microbubbles should not be present in the left side of the heart because of filtering and absorption in the pulmonary capillary bed. The presence of contrast in the left side of the heart after an intravenous injection of agitated saline, therefore, is a very sensitive marker for the existence of a right-to-left intrapulmonary or intracardiac shunt (123). Likewise, the presence of contrast in the right side of the heart after a left heart injection (e.g., in the operating room or cardiac intensive care unit through a left atrial line) is indicative of an intracardiac left-to-right shunt.

Technique

First, the injection site should be considered. For example, a right antecubital injection is sufficient if one needs to opacify the right heart for investigation of an intracardiac right-to-left shunt. However, if one is suspecting drainage of a LSVC into a coronary sinus or the LA directly, the injection site should be through the left antecubital vein to ensure that “contrast” enters the LSVC. In this instance, a right antecubital vein injection would not ensure opacification of a LSVC since the “contrast” would pass through the right innominate vein and preferentially enter the RSVC bypassing a communicating vein (which may not even be present) and the LSVC. In the case of unusual Glenn and Fontan connections it may be necessary to inject into a lower extremity vein to preferentially fill the left pulmonary artery. Sometimes agitated saline contrast should be administered through central catheters during cardiac catheterization, for example, to pinpoint the exact location of a Fontan leak.

Two syringes (one empty, the other filled with saline [~3 mL for newborn, ~20 mL for adult]) are connected to a stopcock. The stopcock is connected to the intravenous line close to its entry into the body. Addition of a small amount (0.25 to 0.5 mL) of the patient’s blood will enhance contrast opacification (124). Agitation is achieved by turning the stopcock off to the patient and forcefully pushing the saline (or saline/blood mixture) alternately between the two syringes for approximately 30 seconds. The sonographer should obtain a view (usually the apical four-chamber view) in which both right and left heart structures are imaged simultaneously so that the contrast can be visualized passing (a) through the right heart to verify that the contrast injection was indeed adequate and (b) through the left heart to verify if a right-to-left shunt is indeed present. The stopcock is then turned on to the patient and the contrast is pushed rapidly into the vein. In older patients, a Valsalva maneuver may be performed to enhance the ability to detect a right-to-left shunt.

Indications

Agitated saline contrast is helpful whenever a right-to-left intrapulmonary or intracardiac shunt is suspected but cannot be detected or definitively diagnosed by standard echocardiographic modalities. These scenarios include the patient with a suspected thromboembolic stroke, unexplained cyanosis,

Figure 8.42. Apical four-chamber view during administration of agitated saline contrast in the left antecubital vein demonstrates dense opacification of the left atrium (LA) supportive of the suspected diagnosis of a left superior vena cava draining directly into the roof of the LA. (This patient also has a moderate pericardial effusion [PE].) LV, left ventricle; RA, right atrium; RV, right ventricle.

suggestion of an intracardiac shunt on an echocardiogram with suboptimal windows, poor oxygen saturations following Glenn or Fontan operation (125), suspected baffle leak following atrial switch procedure for transposition, suspected unroofed coronary sinus, and liver disease with suspected hepatopulmonary syndrome (126,127) (Fig. 8.42).

With intrapulmonary shunts, as seen in pulmonary arteriovenous malformations occurring in cavopulmonary connections and in the hepatopulmonary syndrome, microbubbles in the left heart usually appear three to four cardiac cycles after the contrast cloud appears in the right heart. With intracardiac shunts such as atrial or VSDs, unroofed coronary sinus, or atrial baffle leak, microbubbles appear in the left heart almost immediately upon appearance in the right heart. The exact site of initial left heart microbubble appearance should also be carefully noted since the location of the right-to-left shunt can be pinpointed to either that level or upstream to it.

Diagnosis of the hepatopulmonary syndrome is one of the leading indications for agitated saline contrast. This syndrome is a well-defined cause of hypoxemia in patients with liver disease and carries an incidence as high as 29% (126). It is due to abnormal intrapulmonary vascular dilation resulting in excess perfusion (of deoxygenated blood) for the given state of ventilation. This pathophysiology is in distinction from that occurring in the other well-recognized cardiopulmonary complication, portopulmonary hypertension, which is characterized by abnormal pulmonary vasoconstriction and obliterative vascular remodeling. Alteration in the hepatic synthesis or metabolism of vasoactive pulmonary substances, nitric oxide and possibly endothelin-1, are believed to be integral to the development of intrapulmonary vascular dilation in the hepatopulmonary syndrome (126,128). A particularly interesting congenital etiology of the hepatopulmonary syndrome is the Abernethy Malformation because its initial presentation is one of dyspnea and cyanosis rather than of frank liver disease (127). The malformation is due to congenital absence of the portal vein, which results in a diversion of portal blood away from the liver and directly into the vena cava.

Transpulmonary Contrast Echocardiography

PRINCIPLE

Unlike agitated saline, commercially available transpulmonary contrast agents consist of a suspension of microspheres designed to pass through the pulmonary capillary bed and densely opacify the left heart structures (129). These microspheres are 10-fold smaller than the microbubbles created with saline agitation

(1 to 10 μ vs. 10 to 100 μ) (129). The microspheres consist of an internal gas (air or fluorocarbon) encapsulated by an external shell (aggregated albumin, galactose, or lipid). After an intravenous injection, the microspheres will follow the downstream course of the blood into the right heart and pulmonary vasculature. The microspheres are sufficiently small and the diffusion of the gas is sufficiently limited by its low partition coefficient that the microspheres pass through the capillary bed into the left heart. Because the acoustic impedance of the microspheres is much lower than that of the blood, the ultrasound waves are scattered and reflected at the microsphere-blood interface.

TECHNIQUE

All contrast agents are activated by suspending the microspheres through agitation of the vial, sometimes with a commercially supplied mechanical agitator. The contrast agent can then be administered intravenously by infusion or bolus. Although pediatric dosages have not been established, 50% of the adult dose produces excellent left heart opacification without side effects (130) (Fig. 8.43). Contrast effect persists for approximately 3 to 5 minutes. The ultrasound system should be set to low power or mechanical index so that bubble destruction is minimized. With this setting, the myocardium will appear black and the contrast-filled cavity will be white. Adverse reactions have not been reported in children. In adults, adverse reactions are extremely rare and when present consist of allergic reaction, headache, flushing, and nausea. In the presence of an intracardiac shunt, the microspheres can bypass filtering by the lung and enter the arterial circulation directly. It is believed that the larger (up to 32 μ) microspheres which constitute a very small percentage of the total suspension and which are normally filtered by the lungs can pass into the left heart and produce arterial occlusions in this setting. Therefore, no transpulmonary contrast agent should ever be administered to a patient with a known or suspected intracardiac shunt.

INDICATIONS

Currently, contrast agents are approved for the use of heart opacification and endocardial visualization only. Therefore, they are indicated when traditional echocardiographic modalities yield suboptimal myocardial and endocardial visualization. Most often this is necessary during stress echocardiography when visualization of all myocardial segments is required to adequately assess integrity or compromise of coronary perfusion (130,131).

Additionally, contrast agents may be beneficial in the evaluation of right ventricular function since the right ventricular endocardium and myocardium can be very difficult to visualize.

DIGITAL ARCHIVING AND TELE-/WEB-BASED ECHOCARDIOGRAPHY

The laboratory of our past collected nondiscrete, analog wave-form signals of varying voltages that were stored to videotape, conforming to the National Television Standards set in the 1940s. Now, the digital laboratory of our present uses technology enabling gray scale storage of each pixel in the echocardiographic image by conversion into a series of binary digits. The depth of binary storage dictates the resolution. For example, an 8-bit depth binary system stores the image as series of eight digits (e.g., 00000000, 00000001, and so on) providing $2^8 = 256$ shades of gray. This level is more than sufficient when one considers that the human eye can distinguish only 50 shades of gray. The digital image has almost complete fidelity to the true real-time image.

Digital imaging comes with a considerable storage burden. Typically, a freeze-frame ultrasound image has 512 lines of information with 512 samples per line, resulting in approximately 262,000 pixels per frame. Each pixel is described by an 8-bit binary system, resulting in approximately 2 million bits of data to describe a single frame. At ultrasound frame rates of 45 frames/s, it therefore requires 283 MB of storage to save a single 3-second (~ 5 beat) sweep. A typical study of 60 to 80 clips and a few still frames approaches 20 to 25 GB of data! Guidelines for the management of this massive amount of digital echocardiographic data have been developed by the American Society of Echocardiography (132).

Compression of digital data aids in practical storage and transmission. There are two types of compression: lossless and lossy. Lossless compression ensures that no data are lost but provides only a modest 3:1 reduction in data storage. Lossy compression (e.g., Joint Photography Expert Group method, or JPEG) reduces data storage by 20:1 allowing transmission of video through computer networks and without loss of image quality compared with super Video Home System (VHS) video (133). The Motion Picture Expert Group (MPEG) method is a second compression process that uses a motion picture prediction algorithm exploiting redundancy between preceding

Figure 8.43. Apical four-chamber views at peak heart rate during dobutamine stress echocardiogram without (A) and with (B) transpulmonary contrast agent. Although the noncontrast image (A) is reasonably clear and most wall segments can be identified, the contrast image (B) makes identification of all wall segments (particularly those at the apex) easy.

Figure 8.44. An M-mode echocardiogram of the left ventricle of a mouse using a high-frequency (40 MHz) transducer demonstrates excellent resolution of the ventricular septum, left ventricular cavity, and left ventricular posterior wall.

and subsequent images, thereby offering better motion-image quality, higher compression ratios (e.g., 1,500:1), and easier integration into a computer network. Disadvantages to MPEG compression are that it is not yet validated for echocardiography, is not standardized within DICOM (the Digital Imaging and Communications in Medicine Standard), and has inferior still-frame image quality (134,135).

Despite the large amount of data created with digital echocardiographic image acquisition, image management has been relatively facile and has indeed improved efficiency in the pediatric echocardiography laboratory (136). Computer technology has continued to improve so that images have been routinely attached to web-based journal articles (137). Importantly, images can be transferred easily through web-based networks and onto personal digital devices allowing for reading of echocardiograms from and in remote sites as long as web access is available (138). Acquiring and reading echocardiograms in this manner has been shown to be diagnostically accurate (139).

Further, this technology has had profound impact on (a) more timely diagnosis of critically ill patients, (b) better determination of need for cardiology consult, and (c) preventing unnecessary transfers for the purpose of merely obtaining an echocardiogram (140–142).

RESEARCH ECHOCARDIOGRAPHY

Because of its ease of use, portability, low cost, absence of side effects, and high diagnostic accuracy; echocardiography is a robust research tool. The American Society of Echocardiography has established guidelines for the appropriate use of echocardiography in clinical trials (143). Echocardiography has been used successfully to provide mechanistic insights into disease processes and therapeutic outcomes, to provide both cross-sectional and longitudinal data in large epidemiologic studies, and to measure functional and structural changes now considered to be end points. The Framingham Heart Study was the first epidemiologic study to use echocardiographic measurements (144). The single largest application of echocardiography in epidemiologic studies has been the measurement of left ventricular mass and its change with antihypertensive therapy (145–149). Recently, the use of echocardiography has been expanded to clinical trials investigating cardiac resynchronization therapy for congestive heart failure. Echocardiography has been instrumental to demonstrate that remodeling due to resynchronization therapy is associated with less risk of subsequent ventricular tachyarrhythmia (150). In addition, echocardiography is the major tool for providing detailed phenotypes for large human genetic studies (151).

The use of echocardiography for any research purpose necessitates establishing methods to limit measurement variability. Intra- and interobserver variability should be measured and repeated periodically. Protocols for training qualification need to be developed. A minimum number of sonographers and readers should be used to limit the effects of interobserver variability. Only contemporary equipment should be used. Digital archiving should be established to provide a bioinformatic data bank of echocardiographic images. These practices

are best established by the creation of a core research laboratory which can guarantee adequate training of peripheral sites and accurate, reproducible data analysis (143,152,153).

Echocardiography has also been instrumental in animal research, most notably in the phenotyping of transgenic mice (154–159). Previous phenotyping methods (Langendorf preparation, histologic examination) necessitated sacrifice of the animal. This prohibited not only acquisition of longitudinal data and also further breeding. Mouse echocardiography is performed using high-frequency transducers (at least 15 MHz) while the animal is anesthetized with 2% inhaled isoflurane and kept warm on a heated examination table. Parasternal and apical images are obtained and quantitative data include left ventricular dimensions, function, mass, and aortic and mitral valve Doppler velocities (Fig. 8.44). If the animal has undergone microcatheterization of the left ventricle or a systemic artery, pressure data can be coupled with simultaneous echocardiographic left ventricular dimensional data to create pressure-dimension loops or end-systolic wall stress data, powerful indices of ventricular function (see above) (Fig. 8.45) (159).

Figure 8.45. Left ventricular pressure-dimension loops in control mice (*thin lines*) and hypothyroid mice (*thick lines*) derived from simultaneous M-mode echocardiography and catheterization of the left ventricle. Afterload was manipulated with phenylephrine and nitroprusside infusion to create a family of pressure-dimension loops from which end-systolic relations can be measured. At any given end-systolic dimension, the end-systolic pressure is less in the hypothyroid mice versus the control mice indicating depressed contractility in the hypothyroid mice. (From Williams RV, Lorenz JN, Witt SA, et al. End-systolic stress-velocity and pressure-dimension relationships by transthoracic echocardiography in mice. *Am J Physiol* 1998;274(Heart Circ Physiol 43):H1828–H1835).

Recently, the development of high-frequency ultrasound transducers (30 to 70 MHz) has allowed imaging of hearts in mouse pups or even mouse embryos (160–166). This echocardiographic technique, more appropriately called ultrasound biomicroscopy, involves mounting the anesthetized pup or pregnant ewe on a microscope stage embedded with heating elements to keep the animal warm and which can be moved spatially in x , y , and z planes using three micromanipulator knobs similar to using a microscope. Embryonic mice imaging is extremely valuable since many transgenic mice models are embryonic lethal. Doppler signals are apparent as early as the eighth embryonic day, essentially the heart tube stage (gestational age of mouse = 18.5 days). Four chambers can be identified with echocardiography at embryonic day 11.5 and septation is evident by ultrasound at embryonic day 13.5. Resolution has improved significantly with these higher frequency transducers such that it will now be possible to phenotype transgenic mice models targeted for maldevelopment of the cardiac valves. Using such equipment, investigators have studied the origins of adult cardiovascular disease. Specifically, it has been shown in transgenic studies, for example, that prenatal diet has profound influences on adult cardiovascular mechanics as assessed by echocardiography (167).

THE FUTURE

For years, echocardiography enjoyed a status to itself as the premier diagnostic modality for pediatric cardiovascular disease. This is no longer true. Now, echocardiography shares the stage of noninvasive cardiac imaging with a variety of other modalities, including cardiac magnetic resonance imaging, positron emission tomography, metabolic imaging, and perfusion imaging. Echocardiographers and other pediatric cardiologists need to understand that these modalities complement, rather than replace, echocardiography. For example, cardiac magnetic resonance imaging excels in imaging both extracardiac anatomy and also the spatial relationships of cardiovascular anatomy in relation to other structures in the thoracic cavity. The former has been difficult and the latter impossible for the pediatric echocardiographer. Because of these complementary niches of the various imaging modalities, patient care has improved to unprecedented levels. Nevertheless, the myriad of diagnostic tests provides echocardiographers with at least two challenges.

First, pediatric echocardiographers must resist complacency. There may be a tendency to become less rigorous during the echocardiographic exam knowing that other imaging modalities may later be employed. If difficult anatomy can be diagnosed accurately with echocardiography, the expense, the inconvenience, and potential risk of other imaging modalities will be avoided. We need to remain compulsive and true to our specialty and continue to bring the same rigor and compulsiveness to the exam that we have employed in the past. This will involve not only efforts at the bedside and in the echocardiography laboratory but also efforts at a more communal level such as the continued development of guidelines and standards for the performance of quality echocardiographic examinations (168,169).

The second challenge is one of “imaging responsibility” to our patients and our health care system. We must realize that we are responsible for recognizing and resisting the lure of employing all of the diagnostic armamentarium available to us. The challenge is to partner with our colleagues managing these other imaging modalities to develop pathways in the diagnostic approach for our patients. Such an approach will necessarily be diagnosis- and age- specific and, indeed, in some instances may not utilize echocardiography. In all cases,

however, imagers must join together to develop strategies that bring the greatest value to the patient...an approach that is most accurate with the least cost.

Because of continued miniaturization of computer and ultrasound equipment, hand-carried ultrasound devices have been used for medical diagnostics. Most of these devices now have the capabilities of even the most technologically advanced ultrasound systems but are the size of a small laptop computer or even a mobile phone. Using such devices, echocardiographers can provide point-of-service care more effectively. More importantly, these devices expand the community that can now receive and benefit from the diagnostic power of echocardiography. In addition, the devices improve diagnostic accuracy by complementing the cardiac physical examination in even tertiary care centers.

Although auscultation has been the traditional foundation of the cardiac physical examination, many primary care physicians and even some cardiologists have imperfect auscultatory skills. For example, diagnostic accuracy of current resident physicians using auscultation alone is notoriously poor (170–172). It is likely that these skills will continue to decline as resident physicians cope with the competing forces of having to learn vast amounts of newer medical information within the time constraints imposed by resident work hour regulations. Hand-carried ultrasound devices extend the diagnostic accuracy of echocardiography from the ultrasound laboratory to the time and place of the physical examination. By complementing stethoscope use with a hand-held system, an examiner can not only hear the heart but see it as well, thereby improving diagnostic accuracy (173). Implementation of a hand-carried ultrasound device program into the medical school curriculum significantly increases the diagnostic accuracy of the physical examination performed by medical students (174). Even the accuracy of the cardiovascular examination performed by board-certified cardiologists is enhanced by their use of a hand-carried device (175,176). In pediatrics, hand-held ultrasound has been shown to have similar diagnostic accuracy as traditional ultrasound systems and its use is speculated to only increase (177).

The increased availability of echocardiography made possible by hand-carried devices has tempted other noncardiac specialists to practice cardiac ultrasound (178,179). While this has the potential benefit of enhancing overall patient care by improving diagnostic accuracy, it also emphasizes the need for responsible practice of ultrasound. It is the duty of the echocardiography community to develop standards for the practice of hand-carried ultrasound and ensure that they are met (180).

The situation is similar to stethoscope use. Most physicians who use a stethoscope are not cardiologists; the diagnostic accuracy of the stethoscope varies according to its user, and cardiologists have greater expertise in its use. Likewise, hand-carried ultrasound devices are currently being used by a variety of health care providers, for example, emergency room physicians, neonatologists, and even robots (181–184).

However, as with the stethoscope, it would be expected and need to be indoctrinated as standard of care, that when a noncardiologist identified a patient with suspected pathology using a hand-held device, the patient would be referred to a cardiologist for further evaluation.

The development and expansion of hand-held ultrasound devices speaks to us as physicians, specifically to the reasons as to why many of us chose medicine as our career. We have a powerful, robust tool in echocardiography; a tool with which we can do much good by providing very advanced medical care to an even vaster population. There is great value in the fact that hand-held devices allow us to provide increased availability to our tertiary care populations at surrounding satellite clinics improving medical care by obviating the need for lengthy, stressful and time-consuming journeys to the central facility. But there is perhaps greater value and meaning in

the fact that hand-held devices allow us to spread echocardiographic technology to those patients who would otherwise never benefit from it — the patients utilizing the underserved urban and rural health clinics and the patients in developing countries (185–187). As investigators from the Cedars Sinai Medical Center state, it is this use of echocardiography that truly makes “an impossible mission possible” (186).

Echocardiographic Assessment of Cardiac Dimensions, Cardiac Function, and Valve Function

Luc L. Mertens ■ Mark K. Friedberg

QUANTIFICATION OF CHAMBER DIMENSIONS AND CARDIAC STRUCTURES

Accurate measurements of valves, chambers, and vessels are essential to the diagnosis and management of patients with congenital and pediatric heart disease. The American Society of Echocardiography published recommendations for quantification of chamber sizes and function in adults (1,2) and for quantification of cardiac structures in the pediatric population (3). One of the important differences between measurements in adult and pediatric patients is the effect of growth or body size on measurements. As dimensions of cardiovascular structures correlate best with body surface area (BSA), indexing the size of cardiovascular structures for BSA has become a commonly used practice. The Haycock formula ($BSA [m^2] = 0.024265 \times \text{weight [kg]}^{0.5378} \times \text{height [cm]}^{0.3964}$) has been recommended for BSA calculation. Correction for BSA is based on the assumption that there is a linear relationship between the cardiac measurement and the BSA. This has been shown to be a simplification as the linear relationship does not hold for the entire spectrum and there is increased variance in the measurements with increasing BSA related to confounding factors like blood pressure, obesity, and physical activity (4). To overcome this limitation, the use of z-scores has been proposed as a practical alternative (4). Z-scores are based on measurements of cardiovascular structures in a normal population encompassing a wide range of BSA. The z-score represents the number of standard deviations a measurement lies from the mean value at a specific BSA. For instance, z-score of -3.5 for an aortic valve annulus diameter indicates that the value is 3.5 standard deviations below the mean value for that particular BSA. Z-scores for different cardiovascular structures have been published (5,6), but the effect of gender and race on cardiovascular measurements may necessitate establishing normal values based on population mix seen in a specific laboratory.

Detailing the measurement of each individual cardiovascular structure is beyond the scope of this chapter. The reader is referred to recently published guidelines for this purpose (3). In this chapter, the evaluation of cardiac function and chamber quantification are discussed in more detail. In congenital heart disease, chamber quantification can be challenging due to the variable shapes of the ventricles including the right ventricle (RV) and the univentricular heart.

The authors acknowledge the contributions of Drs. Kimball and Michelfelder to this chapter in the previous edition.

QUANTIFICATION OF THE LEFT VENTRICLE

The importance of accurately measuring left ventricle (LV) size cannot be overstated. Measurement of LV chamber dimensions at end systole and end diastole (linear dimensions, areas, or volumetric measurements) are used to assess LV remodeling (degree of LV dilation) and function. Measurements of LV wall thickness and mass are important to identify LV hypertrophy.

Linear measurements of LV chamber size and wall thickness have been traditionally obtained using M-mode measurements from the parasternal short- or long-axis views just below the tips of the mitral valve leaflets (Fig. 9.1). M-mode measurements have a very high temporal resolution albeit at the expense of low spatial resolution. It can be difficult to obtain a perpendicular M-mode through the LV resulting in oblique planes that overestimate LV dimensions and increase measurement variability. If not well standardized, M-mode measurements can be highly variable. This was shown by Lipshultz et al. (7) who compared the M-mode measurements made in local echocardiography laboratories and in a core laboratory. This study showed poor agreement between the core laboratory and local laboratory measurements with relatively wide limits of agreement. To overcome these problems, the recent American Society of Echocardiography recommendations suggested using measurements obtained from two-dimensional (2-D) imaging in place of M-mode for LV chamber quantification. Two-dimensional short-axis imaging just distal to the mitral valve leaflets is recommended (Fig. 9.2) for measuring the internal LV diameter and the inferolateral and septal wall thickness at end diastole and end systole. However, there are inadequate data to determine if 2-D linear measurements are indeed more reproducible than those obtained by M-mode. Another limitation is that currently all published normal z-score data are based on M-mode measurements and not on 2-D imaging. Following these recommendations, new normal data sets of cardiac dimensions will hopefully be obtained.

2-D and 3-D Techniques

Beyond linear measurements of LV dimensions, it is also possible to calculate LV volumes using either 2-D or 3-D techniques. Two 2-D techniques (the area-length method and the biplane Simpson's method) are currently recommended. The area-length method requires measuring the LV major-axis length from a subcostal or apical four-chamber view combined with an area calculation from a subcostal or parasternal short-axis view. The volume is calculated using the formula $LV \text{ volume} = 5/6 \times CSA \times LV \text{ length}$. As a geometrical formula, this requires a normal LV shape. The biplane Simpson's method is based on summation of disks and requires delineating the endocardial borders in the apical four-chamber and

Figure 9.1. M-mode measurements. M-mode measurement is obtained from a parasternal short-axis view of the left ventricle just inferior to the mitral valve leaflets. End-diastolic (at the QRS complex) and end-systolic (at point of minimal diameter) measurements are obtained and fractional shortening and ejection fraction are calculated. EF, ejection fraction; IVSd, inter-ventricular septum at end diastole; LVPWd, left ventricular posterior wall thickness at end diastole; LVIDs, left ventricular end-systolic dimensions; %FS, percent fractional shortening; SV, stroke volume; LVD Mass, left ventricular mass.

Figure 9.2. Two-dimensional measurement of LV dimensions. The left ventricular end-diastolic dimension (LVEDD) is measured from a parasternal short-axis view just inferior to the mitral valve leaflets.

two-chamber views (Fig. 9.3). Therefore, images should be optimized to allow delineation of the endocardium and LV length as suboptimal border detection and foreshortening of the LV are major problems that result in underestimation of the LV volumes. There have been only a few studies that have investigated the reproducibility of these volumetric methods in the pediatric population. Their accuracy was studied in an adult population where the biplane Simpson's method for calculating LV volumes was compared to cardiac magnetic resonance imaging (MRI) in patients after acute myocardial infarction (8). This study showed a relatively weak correlation ($r = 0.61$, $p < 0.01$) between the echocardiographic and

MRI measurements suggesting that the biplane Simpson's method is not very accurate and the agreement between measurements is not very strong. The accuracy and reproducibility of these measurements is crucial as LV volumes are used for therapeutic decisions (for instance, LV end-systolic volume in aortic regurgitation). These measurements are also used for calculating ejection fraction (EF) as discussed below. The smaller the LV, the larger is the effect of the measurement error. This is especially important in the borderline LV in patients with aortic stenosis where LV volume calculations may determine a biventricular versus a univentricular treatment approach.

Figure 9.3. Use of biplane Simpson's rule in calculating left ventricular (LV) volume in patients with severe LV dysfunction. The first two images from the left show the apical four-chamber view in end diastole and end systole, respectively. The next two images are obtained from the apical two-chamber view also in end diastole and end systole, respectively. LV volumes in end diastole and end systole can be calculated. Based on the biplane measurements, the LV ejection fraction in this example is 22%.

Figure 9.4. Three-dimensional (3-D) echocardiography to assess LV volumes. Three-dimensional echocardiography and (semi-) automated analysis of 3-D volumes is used to measure LV volumetric changes throughout the cardiac cycle. The images represent an apical four-chamber (left upper), an apical two-chamber (right upper), and an apical three-chamber (left lower) cut through the LV volume. The planes through the volumes are illustrated in the right lower panel. On the right of the images, the result of volumetric analysis is shown. LVEDV, left ventricular end-diastolic volume; LVESV, left ventricular end-systolic volume; EF, ejection fraction; SV, stroke volume; CO, cardiac output; HR, heart rate. The lower panel shows the volume–time curve.

Calculating volumes based on 2-D images will always be influenced by assumptions of LV shape and geometry. Three-dimensional echocardiography overcomes this problem as full 3-D volumetric data sets can be obtained using newer generation matrix probes. Most ultrasound systems calculate LV volumes using (semi-) automated analysis algorithms (Fig. 9.4). This results in improved reproducibility as it eliminates observer bias in determining endocardial borders. Hence, the intra- and interobserver variability of 3-D methods are much lower compared to 2-D-based volumetric calculations. Moreover, 3-D echocardiography is more accurate for determination of LV volumes than 2-D when compared to cardiac MRI (9–11). In a pediatric population, 3-D echocardiography has been shown to be the most reliable method for quantification of LV volumes (12). Therefore, it is likely to replace other methods in the foreseeable future. It is important to recognize, however, that the feasibility of the 3-D methods is limited as it is not always possible to obtain good quality 3-D data sets in every patient.

Left Ventricular Mass

Calculation of LV mass can also be useful in pediatric patients. In patients with arterial hypertension, LV mass indexed for BSA or height has been shown to correlate well with disease severity and has diagnostic and therapeutic implications (13). LV mass is usually calculated using the Devereux formula ($\text{LV mass} = 0.8 \times \{1.04[(\text{LVIDd} + \text{PWTd} + \text{SWTd})^3 - (\text{LVIDd})^3]\} + 0.6 \text{ g}$, where LVIDd is the left ventricular end-diastolic dimension, PWTd is the diastolic posterior wall thickness, and SWTd is the diastolic septal wall thickness) from M-mode or 2-D echocardiography. As LV mass is strongly related to body size, various methods have been proposed to correct LV mass for body size. The best correction in the adult population seems to be to index LV mass in grams by height in meters to the 2.7th power (1). Khoury et al. (14) showed that this correction works well for

children >9 years of age but that below that age, there is a significant variation for this index in normal controls. Foster et al. (13) have recently shown that in a pediatric population LV mass-for-height centile curves (and z-scores) are the better method for normalizing LV mass.

The 2-D-based method only works for concentric hypertrophy as it assumes that the LV walls are homogeneously thickened. This assumption is often inaccurate as even in arterial hypertension the basal LV septum is often thicker than the rest of the LV walls, resulting in overestimation of overall LV mass by the Devereux formula. The formula cannot be used in patients with asymmetric hypertrophic cardiomyopathy. Three-dimensional methods can also be used to quantify LV mass and have been shown to correlate better with MRI measurements of LV mass as they are less dependent on geometrical assumptions (15).

QUANTIFICATION OF THE RIGHT VENTRICLE

Assessment of RV dimensions and volumes is even more challenging compared to the LV due to its more complex geometrical shape (difficult to describe by a simple geometrical formula) and anterior position into the chest (anterior wall in the near field of the ultrasound beam reducing spatial resolution) (16). The American Society of Echocardiography has published recent guidelines for assessment of the right heart in adults (2). The American Society of Echocardiography pediatric guidelines also contain updated recommendations for measuring RV dimensions and functions (3). Linear measurements have been used to assess RV size. In the pediatric recommendations, various measurements obtained from the apical four-chamber view have been proposed (Fig. 9.5). These include measuring RV end-diastolic diameters at the basal and midcavity levels, RV end-diastolic length, and also end-diastolic and end-systolic RV areas. A problem with these measurements is the lack of normal data precluding calculation of z-scores. Another problem is that measurements from the apical four-chamber view include only the inlet and the apical portions of the RV and do not account for the RV outlet. Therefore, measurements of the RV outflow tract from either a parasternal short-axis or long-axis view should be made. Z-scores are available for RV outflow end-diastolic dimensions from M-mode, but these mainly reflect RVOT dilation and do not portray remodeling of the remainder of the RV cavity. All 2-D-based methods have been shown to underestimate RV volumes when compared to cardiac MRI volumetric calculations. This is mainly due to foreshortening in the 2-D images (it can be difficult to image the true RV apex by echo) and difficulties in defining the endocardial borders. The RV wall is relatively thin (compacted myocardial thickness of around 3 to 5 mm in the adult heart) and has coarse trabeculations causing variability in endocardial border definition. Also for the RV, 3-D echocardiography is a promising tool for assessing RV volumes. Specific analysis software has become available for quantifying RV volumes from 3-D data sets. Full volumetric acquisition can be difficult, especially when the RV is very large, which limits the feasibility of the 3-D methods. Studies have shown that good quality 3-D data sets can only be obtained in 55% to 75% of patients (17–19). A second problem is that 3-D methods tend to underestimate RV volumes compared to cardiac MRI in patients with congenital heart disease (17–19). Studies have suggested that the larger the ventricle, the more important the underestimation. This is probably related to difficult visualization of the endocardial borders as well as the anatomical landmarks like the pulmonary valve.

Figure 9.5. Measurement of right ventricular (RV) 2-D dimensions. From the apical four-chamber view, RV width is measured just below the tricuspid valve (RV1) and in the mid part of the RV (RV2). RV length is also measured just after tricuspid valve closure from the mid of the tricuspid valve to the apex of the RV.

QUANTIFICATION OF THE UNIVENTRICULAR HEART

Assessing chamber dimensions of the univentricular heart can be challenging due to the variable morphology. First, it is important to know whether the morphology of the dominant ventricle is that of a left, right, or indeterminate morphology. The methods used for measuring the right and left ventricles can be applied to the univentricular heart, but “normal” values for the univentricular heart of either LV or RV morphology are unavailable. Moreover, the size of the ventricle will be influenced by the type of palliation and associated volume loading. A shunted single ventricle will be larger compared to the same ventricle after total cavopulmonary anastomosis. Three-dimensional volumes can also be calculated based on full volumetric data sets. It should be noted, however, that the software used for (semi-) automated calculation of LV and RV volumes assumes a specific geometric shape and has not been validated for single ventricles. Soriano et al. used the method of disk summation to measure the volumes of single ventricles (20). The echocardiographic results were accurate when compared to the MRI results but the method requires extensive off-line manual tracing and processing, limiting its application in clinical practice.

EVALUATION OF SYSTOLIC VENTRICULAR FUNCTION

When evaluating systolic function, it is important to consider the different levels evaluated by the various functional indices. Overall cardiovascular function can be defined as the delivery of blood to the tissues at a rate commensurate with oxygen consumption. This integrates cardiac and vascular function. To describe cardiac function, a distinction between ventricular and myocardial function can be made. Ventricular function is the pump activity generating an adequate cardiac output at low filling pressures. Myocardial function is the phasic shortening and force generation at the fiber or segmental level, followed

by lengthening and force decay. Cardiac function can thus be studied at the level of fiber mechanics, regional or segmental myocardial function, and global pump function (Fig. 9.6). At each level (fiber, segment, or ventricle), there is a component of force development and resulting deformational changes. *Fiber mechanics* describes the relationship between active myocardial fiber force development (contractility) and fiber shortening. The degree of shortening is influenced by the precontraction muscle length (preload) and by the force opposing shortening after the onset of contraction (afterload). The frequency of stimulation will also influence fiber shortening as increased frequency results in increased contractile force development (force-frequency relationship). Echocardiography cannot directly study fiber mechanics. At the level of *regional or segmental* function, regional force development within a segment will result in regional myocardial deformation. At the segmental level, myocardial force is better described as regional wall stress that is influenced by active contractile force development, pressure, wall geometry (wall thickness, regional wall curvature), and segmental interaction. Current echocardiographic techniques allow quantification of regional myocardial deformation as segment shortening, thickening, and rotation (also called regional myocardial strain or deformation). This allows study of regional ventricular wall mechanics. Global pump function is the product of interaction between the different contractile segments resulting in ventricular pressure generation and, when the outlet valve opens, in ejection of blood from the ventricle. On the pump level, ventricular performance is determined by myocardial function (influenced by preload, afterload, and heart rate) and efficient segment interaction (synchronicity of contraction). When interpreting an echocardiographic index of global function, such as EF, it is important to understand that it is influenced by myocardial function and its determinants, synchronicity of contraction, and global ventricular geometry. An EF of 45%, for example, has a completely different implication in a ventricle with severe mitral regurgitation, LV dilation, and left bundle branch block compared to the same EF in a patient with severe aortic stenosis and normal conduction. For interpretation of measurements, it is important to know which physiologic parameters influence the echocardiographic parameters. All too often, measurements are determined to

Figure 9.6. Assessment of ventricular function from fiber to pump level. At the fiber level, active force development results in fiber shortening. This relationship can be studied in muscle strip experiments. On the segmental level, regional wall stress is the composite of regional force development and loading on the regional segment. Force development in a segment will result in segmental deformation. Echocardiographically, regional wall motion and deformation can be studied by tissue Doppler and myocardial-deformation imaging. On the pump level, generation of ventricular pressure results in ejection of blood. This can be assessed using ejection parameters like ejection fraction by echocardiography. Invasively this can be studied by pressure-volume loops.

be indices of “contractility,” while there are very few, if any, that are not influenced by loading conditions. Knowledge on the reliability, reproducibility, and accuracy of the methods to assess ventricular function will also influence interpretation of the results. This is especially important for serial evaluation of patients over time. A program of continuous quality improvement for an echocardiographic laboratory should include regular evaluations of the reliability of the measurements in the individual laboratory (21).

A wide variety of different echocardiographic parameters and indices have been developed for assessing ventricular function. This in itself indicates that no single parameter adequately provides all the necessary information. The echocardiographer needs to integrate information from different parameters to comprehensively describe systolic function. In this chapter, the most commonly used indices will be discussed with a description of their measurement, reproducibility, accuracy, availability of normal values, and the influence of loading conditions.

The most commonly used parameter for assessing LV function, probably is percent shortening fraction (%SF) defined as the percentage change in LV dimension from end diastole to end systole. Percent shortening fraction was traditionally measured using M-mode echocardiography from either the parasternal long-axis or short-axis view just below the level of the mitral valve leaflets. The recent recommendations for quantification advise measuring %SF based on 2-D short-axis cuts (either parasternal or subcostal) through the LV. The disadvantage of using 2-D instead of M-mode is the lower temporal resolution. This can be an important problem at higher heart rates, especially in neonates. It can also be difficult to identify end diastole and end systole on 2-D short-axis views. Percent shortening fraction is defined as

$$(\text{LVEDD} - \text{LVESD}) / \text{LVEDD} \times 100$$

where LVEDD is the left ventricular end-diastolic dimension and LVESD is the left ventricular end-systolic dimension. The normal value ranges between 28% and 38%. Values <28% suggest reduced systolic function, while values >38% indicate hyperdynamic function. In most patients, %SF is relatively easy to measure yielding high feasibility. After adequate standardization of acquisition and analysis, variability should be between 10% and 15%. Percent SF has important limitations that should be taken into account when used for clinical decision making. First, %SF measures the apposition of two opposing walls (basal septum and inferolateral wall) as a measure of global systolic function. This assumes that there are no regional differences in wall motion while, in reality, different conditions are associated with regional wall motion abnormalities. In congenital heart disease, hypokinesia and dyskinesia of the interventricular septum occur in the presence of RV volume loading (e.g., large atrial septal defect). This can cause paradoxical septal motion with the septum moving away from the inferolateral wall during systole (Fig. 9.7). Paradoxical septal motion can also be present in the immediate postoperative (post bypass) period and in the presence of left bundle branch block where maximal systolic motion of the inferolateral wall and septum do not occur simultaneously. All these conditions affect measurement of %SF. In cases of regional myocardial dysfunction, such as after myocardial infarction where the inferolateral and basal septum are not involved, measurement of %SF can overestimate global function. Percent SF is also influenced by preload and afterload and does not directly reflect intrinsic myocardial function. Volume loading will generally increase %SF. An example is the increased %SF in patients with mitral and aortic regurgitation. Pressure loading generally decreases %SF, especially when acute changes occur. A typical example would be an acute increase in arterial blood pressure resulting in an

Figure 9.7. Paradoxical motion of the interventricular septum in a patient with a large atrial septal defect. M-mode obtained from a parasternal short-axis view through the dilated RV and smaller LV. The arrows show the motion of the interventricular septum in the direction of the RV in systole. This paradoxical systolic motion makes it impossible to use shortening fraction as a measure for LV systolic function in this setting.

immediate decrease in %SF. This does not reflect an acute decrease in myocardial contractility but rather the increased loading on the heart. A final important limitation is the dependency of the calculation on LV geometry. When hypertrophy of the wall occurs, as happens in the context of chronic arterial hypertension or hypertrophic cardiomyopathy, endocardial changes and dimension changes are influenced by the thickened wall resulting in an overestimation of systolic function.

Ejection fraction is a volumetric measurement reflecting the percentage change in LV volume from end diastole to end systole. It is defined as

$$EF = (LVEDV - LVESV) / LVEDV \times 100$$

where LVEDV is the LV volume at end diastole and LVESV is the LV volume at end systole. LV volumes can be calculated using M-mode echocardiography, 2-D echocardiography, and 3-D echocardiography. As previously mentioned, the recommended 2-D-based methods are the area-length method and the biplane Simpson's method to quantify EF. Three-dimensional echocardiography has been introduced more recently and has been shown to be more reproducible compared to the biplane Simpson's method. Normal values for EF range between 54% and 75%. EF is a good parameter for global pump function and takes into account regional wall motion abnormalities. Like %SF, the method is load dependent with increased volume loading resulting in higher EF and increased pressure loading decreasing EF.

VCF–End-Systolic Wall Stress Relationship

To overcome the load dependency of the SF and EF measurements, alternative methods have been developed that attempt

to correct for the effect of afterload or wall stress. The velocity of circumferential fiber shortening (VCF) measures the velocity of dimensional changes during ejection. Fiber shortening only occurs during ejection and therefore the mean VCF shortening can be calculated as

$$VCF = \%SF / \text{ejection time}$$

ET can be calculated from an M-mode of the aortic valve with very high temporal resolution. VCF_c should be corrected for heart rate as fiber shortening is influenced by heart rate. The heart rate corrected value can be calculated as

$$VCF_c (\text{circ} / \text{s}) = [(\%SF) \times (RR)^{0.5}] / (ET)$$

where SF is shortening fraction, RR is R to R interval, and ET is ejection time. The corrected VCF_c is relatively insensitive to preload changes but highly sensitive to changes in contractility and afterload. When corrected for afterload, the measurement thus becomes a good parameter for contractility. The problem is how to clinically define afterload. As “fiber shortening” is calculated by measuring ventricular dimensional changes, the same assumptions can be made to calculate “wall stress.” This is based on the Laplace formula where wall stress in a passive tube is related to ventricular pressure and cavity size and inversely related to wall thickness ($\sigma = (Pr)/2h$). Higher ventricular pressure and larger ventricular size increase wall stress while a thicker wall reduces wall stress. Assumptions for both meridional and circumferential wall stress can be derived from M-mode measurements, pressure measurements, and initially, carotid pulse tracing was used to estimate end-systolic wall stress. While peak stress determines the degree of hypertrophy, end-systolic stress is the most important parameter determining systolic shortening (22). The formula that is used to calculate meridional (longitudinal) end-systolic wall stress is

$$ESWS (g / \text{cm}^2) = [1.35(Pes)(LVES)] \div [(4)(hes)(1 + hes / LVES)],$$

where 1.35 is the conversion factor from mm Hg to g/cm^2 , Pes is the end-systolic pressure derived from linear interpolation of the dicrotic notch on the pulse trace assigning the systolic blood trace to its peak and the diastolic pressure to its nadir, LVES is the left ventricular end-systolic dimension, and hes is the left ventricular end-systolic wall thickness. Circumferential end-systolic wall stress can also be calculated with the addition of the LV long-axis end-systolic length from the mitral annulus to the LV apex in the apical four-chamber view (L). Thus, circumferential $ESWS (g/\text{cm}^2) = [(1.35)(Pes)(LVES/2hes)] \times [1 - (LVES)/2(L)]$. Both parameters can be obtained from an M-mode echocardiogram of the LV with simultaneous indirect carotid artery pulse trace and blood pressure determination. This makes the method quite cumbersome. Simplified versions include using mean or peak systolic pressures instead of end-systolic estimated pressures (23). Colan et al. (24) found a direct negative correlation between VCF_c and end-systolic meridional wall stress. This seems logical as higher afterload can be expected to reduce the velocity of fiber shortening for the same myocardial contractility. The relationship between VCF_c and end-systolic wall stress within the normal range has been published (24,25).

Abnormal LV contractility is defined as values for wall stress versus VCF_c falling below the normal expected range. In younger children, the linearity of the relationship was questioned and it was shown that wall stress as calculated in the formula misrepresents afterload in children and young adults

with abnormal left geometry (26). The relationship between VCF_c and wall stress only holds with a normal wall thickness-to-chamber ratio. When this ratio is increased (e.g., hypertrophic cardiomyopathy), meridional wall stress underestimates fiber stress; when the ratio is decreased (e.g., dilated cardiomyopathy), meridional wall stress overestimates fiber stress. The method has been applied in a number of different clinical conditions, especially for the evaluation of cardiac contractility in pediatric patients exposed to anthracyclines. Lipshultz et al. (27) demonstrated that the velocity of fiber shortening versus wall stress is a useful index for following patients after exposure to anthracyclines. Before the wall stress- VCF_c relationship (or contractility) becomes abnormal, an increase in wall stress is measured in some postchemotherapy patients, mainly related to a change in wall thickness-chamber dimension ratio (28). Overall, the added benefit of measuring and calculating the VCF_c relationship is still uncertain. More advanced calculations have been proposed to calculate midwall shortening and even fiber stress, but, apart from use in research, the clinical applicability and the use of these methods in clinical decision making are currently limited, and clinical decision making is still mainly based on calculation of EF.

Doppler Indices of Ventricular Function

Measurement of EF and %SF provides information on global pump function based on dimensional changes. Derived parameters such as VCF_c and wall stress were developed in an attempt to yield information on myocardial and even fiber function. As all these parameters are based on calculations involving geometrical dimensions, their use in congenital heart disease is limited. As an alternative to measuring geometrical changes, Doppler data have been used to quantify ventricular systolic function. Initially, blood pool velocity measurements were made, and more recently tissue Doppler was introduced to measure the velocity of myocardial motion. The advantage of these methods is that they can be obtained independently of ventricular geometry.

One of the proposed blood pool measurements is *maximal* dP/dt based on a CW Doppler signal obtained through an AV-valve regurgitant jet. From invasive pressure measurements, the maximal rate of rise in LV pressure during the isovolumic contraction period (dP/dt_{max}) has been used as an invasive index for LV function. As Doppler velocity measurements represent pressure gradients, the slope of the CW regurgitant jet represents the speed of pressure rise within the ventricle. Practically, dt is calculated between 1 m/s and 3 m/s; dP between those two time points calculated by the Bernoulli equation is 32 mm Hg. dP/dt can then be calculated by the following formula: $dP/dt = 32 \text{ mm Hg/time interval in seconds}$. In the normal LV, dP/dt is 1,200 mm Hg/s or more. The same calculation can be applied to the RV or the univentricular heart. As dP/dt is measured before aortic valve opening, it is independent from changes in afterload but its measurement is influenced by preload changes. As the time interval measured on the Doppler trace is very short and the settings used to obtain the spectral Doppler tracings can be variable, the reliability and accuracy of the method are limited. This confines its use in daily clinical practice. Assessment of cardiac function by measuring blood flow velocity during ventricular ejection is another logical approach. Doppler signals across the aortic and pulmonary valves can provide timing intervals that are used to assess ventricular function. The time period between the onset of the QRS-complex and the onset of outflow is called the pre-ejection period. This period shortens when the function improves. When the pre-ejection period is corrected for ET, the PEP/ET ratio is a parameter for systolic function. One of the problems is that ET is very sensitive to afterload changes and is heart rate dependent. Moreover, the PEP time interval is short and

its measurement influenced by the spectral Doppler settings. A logical next step is to combine inflow and outflow Doppler measurements in the assessment of ventricular function. The myocardial performance index (MPI) was introduced as a nongeometrical index that incorporates both systolic and diastolic time intervals in expressing global ventricular function (29). MPI is defined as

$$(ICT + IRT) / ET$$

where ICT is the isovolumetric contraction time, IRT is the isovolumetric relaxation time, and ET is the ejection time (Fig. 9.8). When systolic dysfunction is present, ICT will prolong and ET shortens resulting in a prolongation of MPI. When diastolic dysfunction is present, the effect of IRT is dependent on the type of diastolic dysfunction. A relaxation abnormality will increase ICT but elevated filling pressures will have the opposite effect as an increase in left atrial (LA) pressure will shorten IRT. Thus, IRT is strongly dependent on preload and filling pressures while ET is influenced by afterload. Normal MPI values for the LV are 0.35 ± 0.03 and for the RV are 0.28 ± 0.04 . MPI has been proposed as an index for global ventricular performance as it incorporates systolic and diastolic function and will also be influenced by loading conditions. MPI has been shown to be a sensitive but not very specific marker of cardiac performance. Nevertheless, in certain diseases like pulmonary hypertension, amyloid heart disease, and pulmonary hypertension, it has strong predictive value (30,31).

Figure 9.8. Myocardial performance index (MPI). The sum of isovolumetric relaxation and contraction time is calculated by measuring mitral valve closure to opening time (MCO) and subtracting the LV ejection time (ET). The difference between these two intervals is the isovolumic time. The total isovolumic time divided by the ET gives the MPI. The MCO is measured on the mitral inflow pattern as shown in the upper part of the picture. The LVET is measured on the aortic outflow as illustrated in the lower part of the figure.

Figure 9.9. Typical longitudinal tissue Doppler tracing obtained in the basal part of the interventricular septum from an apical four-chamber view. Alignment with longitudinal LV motion is extremely important to obtain reliable measurements. Peak systolic velocity (S') (3), peak early diastolic velocity (E') (1), and peak late diastolic velocity (A') (2) are measured.

Apart from measuring flow velocities, Doppler has also been used for measuring myocardial velocities or tissue Doppler velocities. Tissue velocities are lower than most blood pool velocities but have higher amplitudes. Thus by adjusting Doppler filter settings, tissue Doppler velocities can be selectively measured (Fig. 9.9). Pulsed-wave tissue Doppler was developed first, followed by color tissue Doppler. Pulsed Doppler typically measures velocities in a single segment while color tissue Doppler measures velocities in an entire wall or chamber. While pulsed Doppler measures peak velocities, color tissue Doppler measures mean velocities. Therefore, color tissue Doppler velocities are approximately 15% to 20% lower than pulsed Doppler velocities. Color Doppler has the advantage of measuring velocities in different myocardial segments simultaneously while pulsed Doppler samples a single segment in a given time. Typically, pulsed tissue Doppler tracings are obtained at the mitral and tricuspid annulus or basal lateral wall and interventricular septal segments to study longitudinal motion in systole and diastole. A typical pattern of myocardial motion comprises an isovolumic spike followed by a systolic velocity wave. The systolic wave can be biphasic, especially in the lateral wall segments. In diastole, early and late

(during atrial contraction) diastolic velocities can be measured. Experimental studies have confirmed that, for normal myocardium, changes in segmental systolic velocities are closely linked to changes in contractility but are also influenced by loading conditions. Cardiac translational motion and tethering between segments (a noncontractile segment passively pulled by a normally contracting segment) also influences tissue Doppler velocities. As a Doppler technique, it is, by definition, angle dependent and influenced by machine settings and technical optimization. When the methods are well-standardized, tissue Doppler velocities can be measured with reasonable intra- and interobserver variability. Differences between different machines from different vendors have been described, especially for color Doppler measurements (32). At present, the use of systolic velocities is limited mainly to the assessment of ventricular dyssynchrony as will be discussed later in this chapter. Diastolic velocities, on the other hand, have become a key component in diastolic function assessment (see below). In the assessment of systolic function, the spike that occurs during the isovolumetric contraction period has been shown to be potentially useful (33). The mean acceleration of this spike, also called myocardial isovolumic acceleration (IVA), can be measured (Fig. 9.10) and has been described to be a relatively load-independent parameter for contractile function. As isovolumic contraction is a short-lived event (30 to 40 ms), calculation of IVA requires obtaining images at high temporal resolution (>200 frames/s) and the reproducibility of the measurements can be difficult if the method is not well-standardized. An interesting physiologic characteristic of IVA is its heart-rate dependency. Contractility increases with heart rate as described by the force–frequency relationship and IVA has been shown to be able to study this relationship in normal children and in disease (34). This indeed may be its main application as, due to its heart rate dependency, baseline values of IVA are highly variable. The measurement thus requires heart rate manipulation with ventricular pacing or exercise testing.

Ventricular Strain and Strain Rate

To overcome the problem of cardiac motion and translation as well as to neutralize the effect of intersegmental tethering, myocardial strain imaging was developed. Strain is defined as the deformation of a myocardial segment and is a dimensionless unit. Strain rate is the speed at which the deformation occurs and is expressed as strain/second. Initially, strain calculations were based on myocardial tissue Doppler velocities by measuring velocity gradients within the myocardium. In the radial direction, for instance, the endocardium moves faster

Figure 9.10. Isovolumetric acceleration measured in the RV lateral annulus from an apical four-chamber view. The measurement is performed using color tissue Doppler traced at high frame rates (>180 frames/s). The acceleration of the isovolumetric spike is measured from the baseline to the peak.

than the epicardium and the gradient between epi- and endocardial velocities correspond to radial strain rate. Temporal integration of the strain rate curve results in the measurement of strain. Tissue Doppler-derived strain measurements are quite cumbersome and require extensive off-line processing with large intra- and interobserver variability if not well standardized. Moreover, tissue Doppler velocities are angle dependent, limiting the measurement of myocardial deformation in certain directions (mainly longitudinal and radial). More recently, it has become possible to measure the strain and strain rate based on speckle tracking imaging. “Speckles” are gray-scale reflectors within the myocardium and their motion can be tracked in two or three dimensions (Fig. 9.11). The change in distance between the speckles throughout the cardiac cycle can be measured and strain and strain rate derived. The advantage is that this technique is angle independent and most vendors have developed a relatively user-friendly software interface that allows calculation of myocardial strain in different directions (longitudinal, radial, and circumferential). If well standardized, the reproducibility is reasonable but there are considerable differences between strain packages from different vendors, especially for radial strain measurements (35). Speckle tracking techniques perform reasonably well for longitudinal strain, but less well for circumferential and especially radial strain. Technical improvements are likely to occur. The first and probably most important application of strain imaging is quantification of regional myocardial function. This is especially useful when regional wall motion abnormalities are present due to regional myocardial perfusion problems or electromechanical dyssynchrony (Fig. 9.12). Other applications mainly relate to the early detection of myocardial

Figure 9.11. Speckle tracking. Speckles are reflectors within the myocardium. They can be tracked throughout the cardiac cycle frame by frame. The motion of the speckles in 2-D or even 3-D space can be used to calculate myocardial deformation. This image is taken from an apical two-chamber view, and speckles within the inferior wall are magnified. The way these speckles move can be traced in 2-D on a frame-by-frame basis as illustrated in the right panels.

Figure 9.12. Longitudinal LV strain in a 13-year-old girl who developed a myocardial infarction based on abnormal origin of the left coronary artery from the right cusp with posterior looping and intramural course. The **left upper panel** represents the strain curves obtained from the apical three-chamber view, the **left lower panel** represents the strain curves obtained from the apical two-chamber view, and the **right upper panel** represents the strain curves from the apical four-chamber view. Longitudinal strain measurements are significantly reduced in the inferolateral wall segments (*light pink and blue areas*). The figure on the **lower right** demonstrates the recommended method for displaying strain data with all 17 cardiac segments portrayed in a bull's-eye type format. This allows an objective quantification of regional myocardial function. In this patient, the *light pink and blue areas* in the inferolateral wall segments represent the extent of the myocardial infarction on regional myocardial function.

dysfunction, where in certain diseases like Duchenne muscular dystrophy and patients exposed to anthracyclines, changes in systolic strain can be observed prior to changes in other cardiac parameters. Using strain imaging, a detailed study of myocardial wall mechanics is possible. When interpreting strain data, it should be remembered that strain measurements are influenced by ventricular size and loading conditions. The clinical usefulness of all deformation measurements still needs to be proven.

Assessment of Right Ventricular Function

The echocardiographic methods to assess ventricular systolic function were mainly developed to assess LV function. The more complex geometry of the RV, its anterior position within the chest, its coarse trabeculations, and its different physiology, make it more difficult to apply these echocardiographic methods for the assessment of RV systolic function (16). Cardiac MRI is considered the current clinical reference standard for measuring RV volumes and EF. By echocardiography, RV function is often assessed by subjective “eyeballing.” A reasonable echocardiographic surrogate for EF is the measurement of percent fractional area change (%FAC) from an apical four-chamber view. The RV end-diastolic area (RVEDA) and RV end-systolic area (RVESA) are measured and %FAC is calculated as $(RVEDA - RVESA)/RVEDA$ (Fig. 9.13). The %FAC has been shown to have a reasonable correlation with MRI EF, but as delineation of the RV lateral wall can be difficult, it can have significant interobserver variability. The %FAC is not very reliable when the RV outflow tract is dysfunctional as this part of the RV is not imaged from the apical four-chamber view and not included in the measurement.

As the RV fibers are more longitudinally oriented, longitudinal deformation in the RV is more important than radial and circumferential deformation, at least in the nonhypertrophied RV. Thus, the study of longitudinal RV function seems more important compared to the study of LV longitudinal

Figure 9.14. Tricuspid annular planar systolic excursion (TAPSE). An M-mode cursor is placed through the tricuspid valve annulus at the RV free wall and longitudinal displacement of the annulus is measured on the M-mode tracing (*lines* on figure). In this case, TAPSE is 2.7 cm, which is within the normal range (>1.7 cm).

function. The easiest method for assessing longitudinal function is by measuring the tricuspid annulus systolic planar excursion (TAPSE) by M-mode (Fig. 9.14). In adults, the normal excursion is >17 mm. For children, TAPSE is dependent on ventricular size and normal values for children have been published (36). TAPSE is easy to measure and correlates relatively well with EF measurements if there is no significant regional RV dysfunction or tricuspid regurgitation. TAPSE is a potentially useful method for serial follow-up of patients.

Figure 9.13. Right ventricular fractional area change (FAC). From the apical four-chamber view, the RV is imaged so that the endocardial borders can be tracked as well as possible. The RV area is measured at end diastole and at end systole and FAC is calculated as a percentage.

Systolic tissue Doppler velocities at the tricuspid annulus can also be measured with the same limitations as for the LV. IVA has been used in the RV but requires heart rate manipulation if the force–frequency response is to be studied. RV longitudinal strain measurements have also been proposed and have been shown to correlate well with global EF in systemic RVs but less well in patients after tetralogy of Fallot (TOF) repair. This is probably related to the influence of more radial and circumferential strain in patients with more hypertrophied RVs (37).

RV volumes and EFs can also be measured by 3-D echocardiography or by 2-D-based 3-D reconstruction methods. Software for analysis of RV volumes is available and the volumes obtained using these methods have been shown to correlate well with MRI-derived volumes (Fig. 9.15). However, feasibility is a problem as it can be very difficult to acquire the entire RV volume in a single volumetric data set. Another problem is endocardial border detection that can be challenging in the low-resolution 3-D data sets. Finally, it has been shown that 3-D echo tends to underestimate RV volumes compared to MRI, especially in dilated RVs.

Systolic Function of the Univentricular Heart

With advances in surgical palliation of univentricular congenital heart disease, patients now survive longer and the univentricular heart must support both the systemic and pulmonary circulations over many years. Functional evaluation of these ventricles is largely based on subjective assessment. Three-dimensional echocardiography using a method of disks analysis has been shown to correlate well with MRI-based volumetric calculations but requires extensive tracing of the myocardium and is cumbersome. Moreover, the feasibility of this method is limited by the difficulty of capturing the entire volume of the dominant ventricle into a single data set. More work is needed to develop a method to assess volumes in single RVs. Tissue Doppler and strain imaging are promising methods to assess myocardial function in single ventricles but one of their major limitations is that abnormal geometry, ventricular size, and loading conditions affect strain and strain rate values. Therefore, at present, there is no adequate quantitative method to assess the univentricular heart.

Ventricular/ventricular Interaction

In congenital heart, the ventricular–ventricular interactions are important for both systolic and diastolic function assessment. The interventricular septum is an important interface between both ventricles: in RV volume overload, the diastolic flattening of the interventricular septum interferes with LV filling and can influence LV output. In case of pulmonary regurgitation after TOF repair, RV dilation has been shown to influence LV filling and pulmonary valve replacement results in better LV filling and improvement in cardiac output (38). Systolic flattening of the interventricular septum is an important phenomenon in RV hypertension that influences LV systolic and also diastolic function (39,40). Description of the septal position in systole and diastole should therefore be part of the assessment of cardiac function. Apart from the influence of the interventricular septum, the epicardial fibers, which are shared between the RV and LV, also influence interventricular cross-talk. In experimental electrically isolated hearts, it has been demonstrated that up to 20% to 40% of the RV systolic pressure and volume output is generated by LV contraction (41,42). How this is important for patients with congenital heart disease needs further exploration. The electrical interreaction between both ventricles is also very important as discussed further in the section on dyssynchrony evaluation.

ASSESSMENT OF VALVE FUNCTION

Semilunar Valves and Great Vessels

Quantitative Morphometric Evaluation

Quantitative anatomic assessment of the proximal great vessels and their branches is important in a number of circumstances. It is routine to perform a quantitative evaluation of the aortic structures from the level of the valve annulus through the distal aortic arch. Evaluation of the aortic root itself consists of 2-D assessment of the aortic annular dimension, dimension of the aorta at the level of the sinuses of Valsalva, and dimension of the sinotubular junction, ascending

Figure 9.15. Three-dimensional echocardiography to calculate RV volumes. This is based on obtaining a full volumetric data set of the RV and using a semiautomated tracking method to measure RV volume. The **left panel** represents the reconstructed RV volume with the tricuspid valve on the right and the pulmonary valve level on the left of the volume. The **right panels** represent the cuts through the volumetric data sets that are traced to reconstruct the RV volume. The **right upper** is the coronal plane, the **middle** the transverse plane, and the **lower** the sagittal plane.

aorta, proximal and distal transverse aortic arch, and aortic isthmus. In general, 2-D axial resolution is superior to lateral resolution. Therefore, aortic root dimensions are best assessed in the parasternal long axis with the proximal ascending aorta and aortic root perpendicular to the ultrasound beam. Different techniques for measuring the aortic root have been proposed and when using normal data, it is important to know which technique was used to establish the reference values. Measurements can be obtained during early to midsystole as suggested by the pediatric guidelines (3), but most of the normal reference papers have used diastolic measurements of the aortic root. Roman et al. (43) and the more recent paper by Gautier et al. (44) both measured the aortic root at end diastole and also used a leading edge to leading edge technique, which means that they included the anterior wall of the aorta in the measurement but not the posterior wall. The alternative technique is to measure the aortic root between the anterior and posterior inner edges. This is the method used in other imaging modalities like cardiac MRI and cardiac CT and the increased image resolution of echocardiography should allow use of the inner-edge technique.

The aortic valve is magnified in the parasternal long-axis view and the annulus measured from the inner edge of the proximal valve insertion hinge point within the arterial root to the inner edge of the opposite hinge point (Fig. 9.16). The sinus of Valsalva and sinotubular junction are also measured from the parasternal long-axis view. To visualize the aortic root and ascending aorta, it may be necessary to move the transducer one or two intercostal spaces higher (high left parasternal view). The ascending aorta is measured at the level where it crosses the right pulmonary artery. Imaging of the transverse arch and isthmus is usually done in long-axis images of the aortic arch from the suprasternal notch window. Measurements should be performed at the level of the proximal transverse arch (between the innominate and left carotid arteries), the distal transverse arch (between the left carotid and left subclavian arteries), and the aortic isthmus (the narrowest segment distal to the left subclavian artery).

The pulmonary valve is best measured from the parasternal long-axis outflow view, although it can also be measured from the parasternal short-axis view (lower resolution) (Fig. 9.17).

Figure 9.16. Measurement of the aortic valve annulus. A zoomed parasternal long-axis view of the aortic valve is used. The measurement is performed in early systole. The measurement is made at the aortic valve hinge points.

Figure 9.17. Pulmonary valve measurement. In this parasternal short-axis view, the pulmonary valve annulus is measured at the hinge point of the valve leaflets in early systole.

The main pulmonary artery can be measured between the sinotubular junction and the bifurcation. The proximal right pulmonary artery is best measured from the suprasternal view where it crosses behind the aorta. The left pulmonary artery is best measured from the suprasternal or ductal view.

Semilunar Valve Stenosis

Prior to measuring gradients, the level of obstruction needs to be determined by 2-D and color Doppler imaging. Subvalvar and supra-valvar stenosis should be excluded. The severity of aortic and pulmonary valve stenosis in pediatric heart disease is based on Doppler measurement of the peak and mean transvalvular gradient. As with all Doppler assessments, interrogation of transvalvular flow jets should be performed with an angle of insonation as parallel to the direction of flow as possible to minimize underestimation of the valve gradient. As such, aortic valve gradients are most accurately assessed from either the apical window or from a high right parasternal window, with the ultrasound plane angled inferiorly toward the ascending aorta (Fig. 9.18). Suprasternal windows can also be helpful. For the pulmonary valve, the parasternal short- and long-axis views can be used and in infants and smaller children, subcostal imaging can be useful. The peak instantaneous Doppler velocity is measured and the gradient calculated using the Bernoulli equation. This is different from the peak-to-peak gradient measured in the cardiac catheterization laboratory by pullback of the catheter across the valve. The peak instantaneous pressure gradient is calculated from the peak instantaneous flow velocity that occurs across the semilunar valve at a single time point in systole. When peak-to-peak gradients are measured by pullback of the catheter in the cardiac catheterization laboratory, the gradient is expressed as the difference between the peak pressure upstream of the valve (or point of obstruction) and peak pressure proximal to the valve, which does not occur simultaneously in the cardiac cycle. The peak-to-peak gradient measured by echocardiography will often be higher compared to the peak-to-peak gradient measured by catheterization. The mean aortic

Figure 9.18. Continuous wave Doppler tracing obtained in patient with aortic stenosis from the right parasternal window with the patient in a right lateral decubitus position. This position and view frequently affords the best Doppler alignment with the aortic stenosis jet. Peak gradient as well as mean gradient are measured on the tracing.

gradient can be obtained by tracing the flow profile. Mean gradients correlate better with peak-to-peak gradients obtained in the catheterization laboratory. For the pulmonary valve, the peak instantaneous gradient correlates better with the peak-to-peak gradient on pullback—and this explains why for assessing severity of pulmonary valve stenosis, the peak instantaneous gradient is used—while for the aortic valve, the mean gradient is considered to better correlate with the peak-to-peak gradient.

When interpreting gradients, it is important to consider the ventricular function. A low gradient across the aortic valve with poor LV systolic function can result in underestimation of the severity of stenosis. Any factor causing increased flow in the LV outflow such as hyperdynamic ventricular function, anemia, and associated aortic insufficiency will result in higher gradients. As cardiac catheterization is often performed under general anesthesia, it is not unusual to find significant differences in the gradient before and after induction of general anesthesia. Another factor influencing the assessment of Doppler gradients in children is the pressure recovery phenomenon. Potential energy is converted into kinetic energy when blood accelerates across the vena contracta. Some of this energy dissipates into heat related to turbulence and viscous losses. Some of the kinetic energy reconverts to potential energy, resulting in pressure increase distal to the stenosis. This phenomenon is more important when the aorta is smaller and results in overestimation of pressure gradients. Other formulas have been proposed that allow better prediction of the catheter peak-to-peak gradient, but have not been extensively validated.

If there is uncertainty regarding the importance of a semilunar valve stenosis, it can also be useful to try to estimate right or LV pressure, using atrioventricular (AV) valve regurgitation. RV systolic pressure can be assessed by measuring the peak velocity of the tricuspid regurgitant jet. The RV systolic pressure = $4 (\text{TR peak velocity})^2 + \text{estimated right atrial (RA) pressure}$. In general, RA pressure is estimated to be around 5 mm Hg unless there is clinical evidence of elevated RA pressure. LV systolic pressure can be estimated based on the mitral regurgitant jet using the same formula. It can, however, be more difficult to estimate LA pressure.

Calculation of Valve Areas

Because of the aforementioned factors influencing calculation of pressure gradients, estimation of aorta valve area is

recommended in the adult patient with aortic stenosis (45). The recommended method to measure aortic valve area is the continuity equation. This equation, based on the principle of conservation of mass, states that with no net loss of fluid from the system, the volumetric flow at area *A* must be equal to the volumetric flow at area *B*. The equation is therefore stated as

$$A_1 V_1 = A_2 V_2,$$

where *A* is the cross-sectional area of either position 1 or 2, and *V* is the mean velocity of the modal spectral profile at either position 1 or 2.

As the mean flow velocity, *V*, equals the velocity–time integral of flow divided by the ET, and as the ETs across both areas 1 and 2 are essentially the same, the continuity equation is further simplified as follows:

$$A_1 (\text{VTI}_1) = A_2 (\text{VTI}_2),$$

where VTI is the velocity–time integral of flow across either area 1 or 2.

The continuity equation is most frequently used in clinical studies to estimate the effective aortic valve area in the setting of aortic stenosis. By rearranging the continuity equation, the effective valve area of a stenotic aortic valve can be solved for as follows:

$$A_{\text{AOV}} = (A_{\text{LVOT}} \times \text{VTI}_{\text{LVOT}}) / \text{VTI}_{\text{AOV}},$$

where A_{AOV} is the cross-sectional area of the effective aortic valve orifice, A_{LVOT} is the cross-sectional area of the LV outflow tract (LVOT), solved by measuring the diameter of the LVOT in the parasternal long-axis view, VTI_{LVOT} is the velocity–time integral of flow across the LVOT, and VTI_{AOV} is the velocity–time integral across the stenotic aortic valve.

Using the continuity equation, it has been demonstrated that the aortic valve areas calculated in children by Doppler correlate well to aortic valve areas calculated by the Gorlin equation on cardiac catheterization, although Doppler methods tend to underestimate catheter areas slightly (46). In normal children and adolescents,

it has been shown that aortic valve area indexed to BSA is approximately $1.33 \text{ cm}^2/\text{m}^2$ (47), which is very close to values obtained in normal adults (48). Due to the potential inaccuracies in measurement of the LV outflow tract and the larger error associated with the assumption that the outflow tract is circular, the calculation of the valve area is not widely applied in pediatric echocardiography. Direct planimetry by 2-D and 3-D methods have been proposed but due to doming, funnel-type opening of the valve leaflets, the actual orifice is difficult to identify and true *en-face* views of the valves are difficult to obtain. Three-dimensional methods could potentially help to resolve this problem but have not been validated in pediatric cardiology.

Aortic Valve Insufficiency

Isolated aortic regurgitation in the pediatric population is relatively uncommon, but it can be seen, particularly in children with bicuspid aortic valves. More often, aortic regurgitation is seen in conjunction with an abnormal aortic valve that features both aortic stenosis and insufficiency. Evaluation of neo-aortic insufficiency, however, can be important following aortic valve replacement by pulmonary autograft (Ross procedure), in hypoplastic left heart syndrome following a Norwood reconstruction or following an arterial switch operation in transposition of the great arteries. In general, methods for assessing aortic regurgitation can be divided into (a) assessment of LV end-diastolic and end-systolic dimensions and volumes (see section above) and (b) assessment of the aortic regurgitation severity using Doppler methods.

Hemodynamically significant aortic regurgitation results in enlargement of the LV with an increase in LV end-diastolic dimensions and volume. In case of preserved LV function, hyperdynamic LV function is often associated with LV dilatation (Frank-Starling relationship) causing the LV end-systolic dimension to remain low. With progressive aortic regurgitation and associated LV dysfunction, the end-systolic dimensions (and volume) will increase. In adult patients, it has been proposed that aortic valve replacement or repair be undertaken for end-systolic dimensions $>55 \text{ mm}$ to protect against irreversible myocardial damage and risk of sudden death (49). In children, a z-score of >4.0 has been suggested but this is not based on good prospective data. Due to the effect of loading conditions on most echocardiographic functional parameters, it is uncertain which parameter best detects early ventricular dysfunction.

Apart from assessing the effect of chronic regurgitation on the LV size and function, the severity of aortic regurgitation needs to be assessed. Different methods should be combined for a com-

prehensive assessment. Pulsed-wave Doppler flow patterns in the distal aortic arch and descending aorta can be used to assess severity of aortic regurgitation. Significant aortic regurgitation results in holodiastolic flow reversal in the distal aortic arch up to the descending aorta at the level of the diaphragm (Fig. 9.19). Color Doppler interrogation of the aortic insufficiency jet itself can also be performed and various measurements made on the color Doppler images: (a) *Jet width or cross-sectional area*. This is measured immediately below the aortic valve, within 1 cm of the valve (for adults). In the long-axis view, jet width relative to the LV outflow tract dimension can be measured. From the parasternal short-axis view, the cross-sectional area relative to the LV outflow tract area can be measured. The criteria to define severe AR are ratios of $>65\%$ for jet width and $>60\%$ for jet area. This has not been well validated in pediatric aortic regurgitation. (b) *Measurement of the vena contracta*. The vena contracta is defined as the smallest diameter of flow at the level of the aortic valve, immediately below the region of flow convergence. It is different from the jet width that is measured in the LVOT. A vena contracta $>0.6 \text{ cm}$ in adults is associated with severe AI but no data are available for children. (c) *CW Doppler of the regurgitant jet*. The best signals are usually obtained from the apical windows. The most commonly used parameter is the pressure half-time of the aortic insufficiency velocity profile (the time required for the initial peak gradient between aorta and LV to decrease by half). A pressure half-time $>500 \text{ ms}$ usually indicates mild AR, whereas a value $<200 \text{ ms}$ is consistent with severe AR. The problem with this measurement is that it is influenced by LV end-diastolic pressure and the presence of diastolic dysfunction. Increased end-diastolic pressure will shorten the duration of regurgitant flow.

Regurgitant volume, regurgitant fraction, and effective regurgitant orifice area can all be directly estimated by a combination of Doppler and 2-D echocardiography. Estimation of regurgitant volume and EROA can also be done using color flow Doppler imaging of the regurgitant jet and the proximal isovelocity surface area (PISA). These methods are rarely applied in pediatric echocardiography laboratories due to high variability and inadequate validation.

Pulmonary Valve Regurgitation

In theory, all the techniques described for aortic valve regurgitation could be used to assess severity of pulmonary valve regurgitation. In practice, pulmonary valve regurgitation is most commonly graded using color Doppler flow. Flow reversal in the pulmonary artery is assessed and, in general, the presence

Figure 9.19. Patient with severe aortic regurgitation. Holodiastolic backflow in the abdominal aorta is shown on the pulsed Doppler tracing in the abdominal aorta. Color Doppler also shows the diastolic retrograde flow in the descending thoracic aorta.

Figure 9.20. Severe pulmonary regurgitation after TOF repair. A wide regurgitant jet can be seen in the main pulmonary artery originating distally from the right pulmonary artery. The Doppler pattern shows the protodiastolic duration of the jet with its termination late in diastole.

of flow reversal in the distal branch pulmonary arteries is seen in severe pulmonary regurgitation (Fig. 9.20). Jet width relative to the RV OFT dimension can be measured. Finally pressure half-time and duration of the pulmonary regurgitant flow relative to the total time of diastole can be used to quantify severity of pulmonary regurgitation. These, however, are influenced by RV end-diastolic pressure. The impact of pulmonary regurgitation on RV dimensions and function can be assessed as discussed in the section on RV volume and function. Based on cardiac MRI data, a RV end-diastolic volume between 150 and 170 mL/m² has been proposed as an indication for pulmonary valve replacement.

ATRIOVENTRICULAR VALVE SIZE AND FUNCTION

Quantitative Morphometric Evaluation

The annuli of the tricuspid and mitral valves have an elliptical and saddle-like shape and are best measured from the apical four-chamber view and parasternal long-axis view (Figs. 9.21 and 9.22). The diameters of the valves should be measured in early diastole at the frame after maximal excursion of the leaflets from inner edge to inner edge at the hinge points of the leaflets. The values should be expressed as z-scores. The area of valves can be calculated using the formula of an ellipse. Planimetry based on

Figure 9.21. Measurement of the tricuspid valve in two planes. **Left panel** shows the apical four-chamber view and **right panel** the parasternal long-axis inflow view. The valve is measured in diastole with the leaflets open.

Figure 9.22. Measurement of the mitral valve in two planes. **Left panel** shows the apical four-chamber view and **right panel** the parasternal long-axis view. The valve is measured in diastole with the leaflets open.

2-D or 3-D images can also be used to measure AV valve size. Tricuspid and mitral valves annular sizes are important in valve disease as well as in the assessment of ventricular size.

Mitral or Tricuspid Stenosis

Mitral and especially tricuspid valve stenosis are rare congenital lesions. Echocardiography is used to define the mechanisms contributing to valvar narrowing and requires a detailed description of the supralvalvar region (supralvalvular ring), leaflets (thickened, reduced mobility), chordae

(short chordae in case of arcade mitral valve), and papillary muscles (parachute mitral valve). In patients with AV valve stenosis, the Doppler flow will usually be turbulent and its velocity elevated. The early peak velocity can be increased in cases of elevated filling pressures associated with LV diastolic dysfunction, which should be distinguished from mitral valve stenosis. The best method to assess AV-valve stenosis severity is by calculation of mean gradients using the mitral or tricuspid inflow signal (Fig. 9.23). For the tricuspid valve, there can be considerable influence of respiration on the inflow gradient with an increasing gradient during inspiration and decreasing gradient during expiration. Therefore, the gradient should be

Figure 9.23. Mitral stenosis. Continuous wave Doppler signal through the inflow in the LV. The mean gradient across the valve is calculated.

averaged over at least three to five cardiac cycles. Heart rate and associated AV-valve regurgitation will also influence the calculated mean gradient. The severity of mitral valve stenosis can also be assessed by calculating the pressure half-time (the time needed for the peak early diastolic pressure to decline by 50%). A pressure half-time <60 ms is normal. A pressure half-time ($T_{1/2}$) >100 ms is indicative of significant mitral stenosis. Based on mitral valve pressure half-time, mitral valve area can be measured based on the formula ($220/T_{1/2}$). However, this calculation is not usually applicable in children due to higher heart rates influencing $T_{1/2}$. Effective orifice size can also be measured by the continuity equation, although again, this is more problematic in children. Direct planimetry based on 2-D or 3-D short-axis views of the mitral valve has been proposed but has not been well validated. Therefore, in practice, the most commonly used method is calculation of the mean gradient across the valve. The presence of an atrial septal defect/patent foramen ovale can lead to atrial decompression and lowering of atrial pressures resulting in a reduction of the gradient across the mitral valve. Therefore, in addition to the heart rate, the presence of an atrial communication should also be noted.

Atrioventricular Valve Insufficiency

In pediatric heart disease, assessment of AV insufficiency continues to be largely semiquantitative based on color Doppler. In adult echocardiography, more quantitative methods have been proposed including measurement of the vena contracta, regurgitant jet area, calculation of the regurgitant volume, regurgitant fraction, and effective regurgitant orifice area from the continuity equation and from the PISA. However, the utility of these indices in children is limited, and none of these have been adequately validated.

DIASTOLIC VENTRICULAR FUNCTION

Diastolic function describes the ability of the ventricles to fill with blood from the atria and pulmonary or systemic veins under low pressure. Echocardiographic assessment of diastolic function is based on Doppler assessment of AV inflow and the pulmonary (or systemic) veins with supplemental assessment by tissue Doppler, color-M-mode, and deformation imaging. Despite the multitude of available indices and techniques, echo assessment of diastolic function remains a challenging area in pediatric cardiology. At the same time, as our understanding of the importance of diastolic function in both acquired and congenital pediatric heart disease evolves, there is a need to correctly assess diastolic function in children.

Diastolic Physiology

Ventricular diastole can be defined as the time between semilunar valve closure and AV valve closure. This period is further divided into isovolumic relaxation, rapid early filling, diastasis, and filling during atrial systole (Fig. 9.24). Although useful, this definition is simplistic in that relaxation begins in some ventricular segments while other segments are still contracting. Moreover, diastolic function is intimately connected to the preceding systole through recoil, restoring forces, and ventricular suction effects that are linked to energy built up in systole and also connected to ventricular contractile synchrony. Likewise, a prolonged systole due to ventricular dysfunction will compromise diastolic duration (50). Thus, systolic and diastolic functions are intimately linked (50,52).

Figure 9.24. Physiologic tracing of left ventricular (solid line), left atrial (dotted line), and aortic (dash-dot line) pressure during the cardiac cycle. Diastole is defined as the time between aortic valve closure (arrow, top left) and mitral valve closure (arrow, bottom right). Isovolumic relaxation (IVRT) occurs between aortic valve closure and mitral valve opening. ECG, electrocardiogram; ICT, isovolumic contraction time.

Diastole is a complex process with both active and passive components. Ventricular relaxation is characterized by a decrease in ventricular pressure for a given ventricular volume. Initially, the pressure decrease is rapid and as the pressure in the ventricle falls below the pressure in the great vessels, the semilunar valves close. Mechanically, this initial decrease in ventricular pressure can be considered the onset of diastole. As the ventricular pressure declines further, it falls below the atrial pressure and the AV valves are swept open by blood rushing from the atria into the rapidly relaxing ventricles. Thus, a period exists between semilunar valve closure and AV valve opening characterized by a sharp fall in ventricular pressure without change in ventricular volume. In fact, most ventricular relaxation occurs in this isovolumic period. As the AV valves open, there is rapid filling in early diastole, which ceases temporarily when ventricular and atrial pressures equilibrate during diastasis. Further filling of the ventricle subsequently occurs during atrial contraction. Thus, early diastole is dependent primarily on ventricular relaxation, while filling in late diastole is determined to a large degree by ventricular compliance, defined as the change in pressure for a given change in volume. Overall, through their effect on the trans-mitral pressure gradient, ventricular relaxation and ventricular compliance are the two major determinants of diastolic function.

The timing and rate of ventricular relaxation are dependent on preload, afterload, myocardial relaxation, and mechanical synchrony. Myocardial relaxation is an active process involving rapid removal of intracellular Ca^{2+} controlled

predominantly by the sarcoendoplasmic Ca^{2+} -ATPase. Development of the sarcoplasmic reticulum and calcium handling in the myocyte is an age-dependent process that is relatively immature in the fetus and neonate. Age will therefore impact the rate of ventricular relaxation and the observed Doppler variables describing this phenomenon (53). The rate of relaxation will also be influenced by the degree of systolic shortening in the preceding cardiac cycle as well as by elastic recoil in early diastole from forces created in systole. In addition, the myocardium has viscous properties that require greater force to induce rapid expansion than more gradual expansion. These properties are likely most important when rapid filling occurs in early diastole and during atrial systole. Passive filling is impacted by atrial pressure, heart rate, and the elastic properties of the ventricle. The degree of ventricular filling during atrial systole is further modified by ventricular compliance and atrial function. The interplay of factors impacting diastolic function and affecting the transmitral gradient is portrayed in Figure 9.25. In turn, ventricular filling pressures are influenced not only by ventricular or myocardial properties, but by a variety of additional factors. This complicates isolated assessment of ventricular and myocardial diastolic properties by echo. Likewise, heart rate has a profound impact on diastolic duration (54,55). Therefore, growth and its associated change in heart rate will influence diastole and its assessment by echo. At high heart rates, there is exponential shortening of the diastolic duration with elimination of diastasis and fusion of early and late AV inflow and tissue Doppler waves into a single summation wave. Fusion between early and late diastolic waves of AV inflow or tissue velocities limits echo assessment of diastolic function in children with high heart rates.

History of Doppler Diastolic Assessment

Our understanding of the progression of LV diastolic dysfunction became clearer in 1992, when Appleton and Hatle (56) described the natural history of diastolic dysfunction. Using Doppler echocardiography, they demonstrated that diastolic dysfunction occurred in progressive sequence that could be characterized by Doppler echocardiography analysis of transmitral and pulmonary venous flow profiles. Subsequent work in additional techniques such as Tissue Doppler Imaging (TDI) (57–59) further refined assessment of diastolic ventricular function.

In adults, ventricular diastolic dysfunction has been classically described as progressing along a spectrum of increasing severity, divided into three main stages. In mild (stage I)

Figure 9.25. Factors influencing diastolic function.

diastolic dysfunction, the predominant abnormality is impaired ventricular relaxation. In moderate (stage II) diastolic dysfunction, pseudonormal function—described below—is noted. In the most severe (stage III) diastolic dysfunction, restrictive physiology is present. A fourth stage of irreversible restrictive physiology is also considered and portrays worse prognosis. Whether this paradigm of progressive diastolic worsening through these defined stages holds true for children is still under investigation. Our impression is that it is less common to see isolated stage 1 diastolic dysfunction in children, except in specific circumstances such as some children with ventricular hypertrophy secondary to hypertrophic cardiomyopathy or systemic hypertension (60). Rather, we often note concomitant abnormalities of relaxation and compliance, with predominance of decreased compliance. Nonetheless, the adult paradigm of staged progression currently provides the best working framework to assess and report diastolic dysfunction and its severity (61).

Echocardiographic Evaluation of Diastolic Function

Regardless of the stage of diastolic dysfunction, a standard protocol for evaluating LV diastolic function in children should be used (3). As no single echo index adequately describes diastolic dysfunction, a comprehensive examination is needed incorporating multiple parameters with interpretation and integration of the information by the echocardiographer. Echocardiographic assessment of diastolic function is usually centered on (a) transmitral Doppler flow, (b) pulmonary venous flow patterns, and (c) TDI of the lateral and medial mitral annulus. Color M-mode and deformation imaging are adjunct modalities.

Transmitral Doppler Flow Evaluation

Transmitral flow is obtained using a 1 to 2 mm pulsed Doppler sample placed between the tips of the mitral leaflets. A normal transmitral Doppler flow pattern (Fig. 9.26) features an early triangular diastolic E wave, with rapid acceleration and deceleration. The E wave includes the flow profile of early ventricular filling, while the E-wave deceleration phase reflects equalization between ventricular and atrial pressures. Therefore, an increase or decrease in filling pressures will shorten or lengthen the E-wave deceleration time, respectively. E-wave deceleration occurs after most early filling has occurred and is largely influenced by ventricular compliance. After cessation of the E wave, there is a period of diastasis (“separation” in ancient Greek), where little or no flow is seen. The quiescence of diastasis ends with the onset of the transmitral “A” wave, which begins after electrical activation of the atria (onset of the ECG P wave) and includes flow occurring during atrial systole. In addition, by enlarging the pulsed-wave Doppler sample volume and positioning it more medially so that it straddles the LV inflow and outflow, a simultaneous display of both mitral inflow and LV outflow can be obtained. The isovolumic relaxation time (IVRT) can then be measured as the interval between cessation of systolic flow and onset of mitral inflow. For a comprehensive diastolic function evaluation, the peak E- and A-wave velocities, E-wave deceleration time, A-wave duration, and IVRT should be measured. The peak E-wave/peak A-wave velocity ratio is also calculated (3). Although not commonly assessed, some authors advocate for measurement of the mitral flow velocity at the onset of atrial contraction. This “E at A” velocity affects the peak velocity and duration of the mitral A wave and hence important parameters such as the E/A ratio, the duration of pulmonary A-wave reversal relative to mitral A-wave duration.

Figure 9.26. Mitral inflow at slow heart rate (panel A): Pulsed Doppler of the mitral inflow. The cursor is positioned at the tips of the mitral leaflets. Early (E) and late (A) diastolic waves are seen. Minimal flow is seen in diastasis—the period between the E and A waves. The isovolumic relaxation time (IVRT), measured from cessation of LV outflow to onset of mitral inflow and E-wave deceleration time (DT) are depicted. Mitral inflow at fast heart rate (panel B). Doppler of mitral inflow. Due to the fast heart rate, there is no diastasis and the E and A waves begin to overlap. At higher heart rates, these will merge into a single inflow wave. The asterisks depicts the “E at A” point. This is the point where the E and A waves merge when the E wave does not reach the baseline.

Pulmonary Venous Doppler Flow Analysis

Pulmonary venous flow is usually assessed from the apical four-chamber view by placing a 5-mm pulsed Doppler sample volume in the right pulmonary vein. The pulmonary venous flow features a low velocity phasic flow pattern consisting of

a systolic S wave, an early diastolic D wave, and a late diastolic reversal during atrial systole (A-wave reversal). During a comprehensive diastolic function assessment, the peak S- and D-wave velocities and the duration and peak velocity of the pulmonary venous A wave are measured, and the S-wave/D-wave velocity ratio is calculated (Fig. 9.27). Of these, the

Figure 9.27. Pulmonary vein Doppler: Pulsed Doppler of a right pulmonary vein obtained from the apical view in a normal child. A systolic (S) and diastolic (D) wave are seen. In adults, a reduced S wave compared to the D wave would be abnormal and suggestive of delayed relaxation. However, this is commonly seen in normal children. The S wave often comprises an early and late component (S1, S2). This can be subtly discerned in the second cardiac cycle. Following the electrocardiographic P wave and atrial contraction, there is a small amount of flow reversal back into the pulmonary vein (AR). The duration and peak velocity of this flow reversal are measured as indirect indicators of ventricular compliance.

duration of the A-wave reversal relative to the mitral inflow A-wave duration is considered most useful as an indicator of ventricular compliance and reflects filling pressures in adults and in children (62). Of note, in the largest study of pediatric echo Doppler diastolic values to date, a small, but important, number of normal children were found to have increased duration of pulmonary vein A-wave reversal (62). Data in healthy infants and young children are limited to a small number of children (63).

Doppler Myocardial Velocity Assessment

TDI is a Doppler modality in which myocardial motion can be displayed both by color Doppler velocity maps and by pulsed Doppler spectral display. Tissue motion features low velocity and high amplitude signals; therefore, TDI presets optimize low-pass filters and lower-gain amplification to allow display of tissue velocities. This is in contrast to blood flow velocities, for which high-velocity and low-amplitude signals require different Doppler settings (Fig. 9.28).

Color tissue Doppler is derived from mean velocities and values are approximately 20% lower than the peak values depicted by pulsed tissue Doppler. Both color and pulsed TDI are easy to acquire and can be readily incorporated into the routine clinical exam. Color TDI is more convenient to interrogate large areas of myocardium in a single acquisition with subsequent off-line analysis of regions of interest anywhere in the data set. However, to date, the largest pediatric data sets in normal children report pulsed TDI values (64–68).

In addition, most literature investigating usefulness of TDI in relation to hemodynamics and in relation to clinical outcomes has used pulsed TDI. Therefore, for clinical assessment of LV diastolic function, it is conventional to use pulsed-wave Doppler assessment of the lateral and medial mitral valve annulus and to obtain the spectral display necessary for diastolic function evaluation (Fig. 9.28). TDI yields an early and late diastolic wave, mirroring AV inflow, but in the opposite direction (from the apical window, diastolic tissue velocities are below the baseline—moving away from the transducer). Typically, the peak tissue E-wave ($E_a[E']$) and A-wave ($A_a[A']$) velocities are measured. While the peak E'/A' -wave velocity ratio can be calculated, most research has focused on the utility of the early diastolic velocity (E'). This early diastolic tissue motion reflects diastolic relaxation and peak E' values correlate with the time constant of pressure decay in the LV (τ) (69). Tissue velocities are influenced by afterload, and although they

are also influenced by preload, they are less so than mitral inflow velocities. As abnormal loading is a hallmark of many types of congenital heart disease, thereby complicating interpretation of diastolic function through mitral inflow patterns alone, tissue Doppler velocities may play a useful adjunctive role. However, it should be noted that tissue Doppler velocities are less influenced by loading when ventricular relaxation is impaired. In the presence of normal relaxation, loading will have a greater influence on diastolic tissue velocities. In adults, out of all the various echo indices, E' is one of the best discriminators between normal and abnormal. Therefore, in the American Society of Echocardiography guidelines, grading of diastolic dysfunction begins with the E' velocity as well as LA volume (61). Whether or not this technique is applicable in children remains to be shown. It should also be remembered that the E' is sampled at a specific location, but is used to reflect on “global” ventricular properties, which may not hold true in all individuals. Importantly, the E' velocity or the related E'/E' ratio has also been shown to have prognostic value in a variety of adult and pediatric conditions including ischemic heart disease, valvular disease, dilated cardiomyopathy, hypertrophic cardiomyopathy, LV noncompaction, transplant rejection, and diabetes (70–75). A major practical advantage of TDI is that it is easy to obtain and yields robust signals, even when imaging windows are poor. High temporal resolution ensures that peak velocities are captured even when heart rates are high. An important pitfall of TDI is that tissue velocities may arise from passive myocardial motion due to translational motion of the entire heart in the chest or tethering of the interrogated passive segment to adjacent actively contracting or relaxing segments. Measurement of longitudinal velocities partly overcomes tethering effects as longitudinal motion is less affected by tethering. Tissue velocities change rapidly over the first year of life and are highly correlated to LV end-diastolic dimensions and mass (65). These characteristics should be taken into account when interpreting E' peak values in children. In addition, the IVRT derived from tissue Doppler imaging (TDI) may be useful as a parameter of LV relaxation (76) and normal data are available in children (77). Likewise, the $IVRT'/IVRT$ has been shown to correlate with LV filling pressures (76).

Estimation of Left Atrial Volume

In the absence of mitral stenosis or mitral regurgitation, estimation of LA volume is one of the most important parameters to assess chronic elevation of LV filling pressures (78).

Figure 9.28. Color and pulsed Doppler in the assessment of diastolic function. Color (panel A) and pulsed (panel B) tissue Doppler sampled at the basal interventricular septum. In the color TDI image, aortic valve opening (AVO) and closure (AVC) are depicted (green lines). Systolic (Sa), early diastolic (E'), and late diastolic (A') waves are seen. Note that tissue velocity directions are a mirror image of atrioventricular valve inflow.

Figure 9.29. Continuous wave Doppler of mitral regurgitation in a child with dilated cardiomyopathy. The duration of mitral regurgitation represents the systolic duration (S). The remainder of the cardiac cycle represents diastolic duration (D). In ventricular dysfunction, systolic duration is prolonged compromising diastolic duration. This problem is aggravated by the relatively fast heart rate of 124 beats per minute in this patient where systolic duration is twice that of diastolic duration.

Normal values have been published in children (79) (Fig. 9.29). As filling pressures are related in part to LV compliance, increased LA volume has been associated with increasing severity of LV diastolic function (80) in a variety of conditions including in hypertrophic cardiomyopathy (79,81,82) and in both adult (81) and pediatric hypertension (83). Because increased filling pressures are related to clinical symptoms and outcomes, LA volume has been correlated to mortality in various types of heart disease in adults as well as in hypertrophic cardiomyopathy (84). LA volume can be measured using the biplane methods of discs (85), imaging the left atrium orthogonally in the apical two- and four-chamber views (Fig. 9.30), by the area length method or by 3-D echocardiography (3,86). Echocardiographic estimates of LA volume correlate well with estimates by cineangiography (87) and computed tomography (88), and can be compared to published normal values (87,89).

Color M-mode

Normal ventricular relaxation propagates from apex to base and, as will be subsequently discussed, is enhanced by recoil and untwisting of the LV. These mechanics produce a suction effect that allows rapid filling of the ventricle at low filling pressures via creation of intraventricular pressure gradients from base to apex. These pressure gradients can be calculated from Doppler by solving for the Euler equation, a derivative of the Bernoulli equation (90). The same phenomenon can be simply imaged by color M-mode as the flow propagation into the LV. This is done most practically by placing a color Doppler map between base and apex and placing an M-mode cursor through the mitral inflow. The color scale is lowered and the slope of the first aliasing velocity line is measured as the propagation velocity (V_p) (Fig. 9.31). The V_p is a measure of LV relaxation and has been found to correlate with tau in children with congenital heart disease (60). As the V_p is related to relaxation, the E/V_p ratio can be used to estimate mean LA pressures much in the same way as the E/E' ratio. Some adult laboratories have proposed using a qualitative assessment of this measure (91), but in children, it has been our experience that qualitative assessment is difficult. In adults, normal values are >50 cm/s. Although one pediatric paper found that age did not significantly impact V_p , as for many diastolic parameters, a large range of values were found in normal children (92). As the mitral leaflets are opened by blood flowing into the ventricle, measuring the slope of mitral excursion in early diastole by M-mode may be a simple surrogate for V_p (93).

Deformation Imaging

The rate of diastolic tissue relaxation can be assessed during the isovolumic relaxation period using speckle tracking to measure the global diastolic strain rate during IVRT (Fig. 9.32). This more direct assessment of LV myocardial relaxation will be less influenced by localized abnormalities at the mitral annulus or basal septum, where the E' tissue velocities are measured (91), but is limited by use of relatively low frame rates in relation to a very rapid event. Likewise, the degree of myocardial expansion (relaxation) at certain time points in diastole can be used as indicators of myocardial relaxation. Accordingly, the percentage of strain in early

Figure 9.30. LA volume by Simpson's method. Left atrial volumes are calculated by Simpson's method of discs. The left atrium is planimetered in two orthogonal planes (four-chamber view, left panel and two-chamber view, right panel) to obtain both area and length. Volume is then calculated as $0.85 A_1 A_2/L$. LA volume > 32 mL/m² are abnormal.

Figure 9.31. The velocity of flow propagation (V_p) into the left ventricle (LV), an index of LV relaxation, is obtained by color M-mode. An M-mode scan line is placed from the LV apex through the mitral valve with simultaneous color Doppler flow. The color scale (Nyquist limit) is lowered until aliasing is obtained. The slope between the first and second aliasing velocity is measured as the V_p . A more shallow slope indicates impaired relaxation. Normal data for pediatric V_p are not available.

diastole has been proposed as an index of relaxation (94). However, in children, diastolic strain and especially strain rate measurements are hampered by poor reliability (35). This is likely related in part to inadequate capture of the very rapid early relaxation, especially in young children, using relatively low frame rates currently accepted for 2-D speckle tracking echocardiography. Strain and strain rate are not currently recommended for routine clinical assessment of diastolic function according to the guidelines of the American Society of Echocardiography (95).

The LV contracts with a twisting motion, and the subsequent rapid untwisting motion in early diastole contributes to LV filling. Twisting in systole and untwisting in diastole is calculated as the net difference in rotation between base and apex. Normal basal systolic rotation is clockwise (when viewed from the apex), whereas the apex rotates in the counterclockwise direction. In diastole, directions are reversed. Ventricular untwisting can be measured by color TDI techniques (96), but is more easily imaged using speckle tracking echocardiography (97) from rotation measured at the base and at the apex in short-axis images. The rate of untwisting may be an even more informative parameter and correlates with tau (98). In normal young children, one study has found especially vigorous untwisting and recoiling of the apex during isovolumic relaxation and early diastole (99). This contrasts a previous study that found slower untwisting during isovolumic relaxation in infants, with subsequent increase over age (100). Decreased rotation mechanics have been demonstrated in various diseases of myocardial dysfunction including hypertension, hypertrophic cardiomyopathy, and nonischemic and ischemic heart disease in adults (101,102), and dilated cardiomyopathy in children (103). However, as untwisting is

Figure 9.32. Left ventricular early diastolic radial strain rate obtained from 2-D speckle-tracking echocardiography in a parasternal short-axis plane at the papillary muscle level. Peak early diastolic strain rate is marked by the arrow. The top left panel is the reference image. The lower left panel depicts strain rate in color M-mode format. The x-axis is time. The y-axis is the various myocardial segments with the top portion indicating the anterospetum and continuing clockwise (around the transverse plane of the LV from top to bottom in the figure). The blue color depicts the diastolic strain rate and gives the same information shown in the curves. Although, this measurement reflects early diastolic relaxation, we do not advocate for its use as a routine clinical parameter as frame rates are low compared to the rapid sequence of the event.

strongly related to systolic twisting and end-systolic volume, it is not a “pure” indicator of diastolic relaxation (97). While rotation mechanics values have now been published in normal children (99), validation studies and demonstration of the usefulness of this index in clinical practice are still lacking.

Normal Echocardiographic Diastolic Function

In the normal LV, ventricular relaxation leads to a rapid fall in LV pressure during isovolumic relaxation creating a pressure gradient in early systole between the left atrium and LV. Early diastolic flow into the LV is driven by this pressure gradient, producing the mitral valve E wave. During diastasis, there is minimal pressure gradient between left atrium and LV with cessation of flow and lack of Doppler signal. During atrial systole, a LA–LV pressure gradient recurs to produce late diastolic filling—the mitral valve A wave.

The normal E-wave/A-wave velocity ratio in children between 3 years of age and adulthood is approximately 2.3 ± 0.6 , with mitral valve A-wave duration of approximately 140 \pm 21 ms (62). The normal pattern of mitral inflow is portrayed in Figure 9.26. It is optimal to interpret the E/A ratio when the mitral inflow velocity at onset of atrial contraction is <20 cm/s. However, this is dependent on heart rate and it is not feasible to lower heart rates in children for the purposes of this examination. Likewise, both IVRT and mitral E-wave deceleration time are heart rate dependent. Nomograms for deceleration time versus heart rate have been published (62). It has been proposed that correcting the IVRT for heart rate by dividing by the square root of the cardiac cycle length identifies a normal heart rate corrected IVRT of 63 ± 7 ms in children from several months

Figure 9.33. Fetal inflow pattern. A typical mitral inflow pattern on a fetal exam obtained from an apical four-chamber view with $E < A$ and prolonged IRTs.

to 20 years of age (104). In infants <2 months of age and in the fetus, myocardial immaturity produces a pattern of impaired relaxation with reversed E and A waves and TDI E' and A' waves. Thus, in the fetus and neonate, E-wave/A-wave ratios <1 and prolonged IVRTs are noted (Fig. 9.33); the degree to which these indices differ from normal children and adolescents is a function of myocardial maturity. Thus these changes are seen more dramatically in the fetus than in the newborn and in the newborn more than in the 2- to 3-month-old infant. The maturation from fetal to childhood patterns generally occurs by 3 months of age (105).

Normal pulmonary venous flow (Fig. 9.27) has typical S and D waves and usually a small atrial systolic A wave. The S wave may have two components: S1 and S2. In younger children, the S-to-D velocity ratio is typically <1, a finding that differs from the older adolescent and adult population for which the S/D-wave velocity ratio in normal subjects is typically >1. The normal pulmonary venous S-wave/D-wave ratio in children 3 to 17 years of age is 0.8 ± 0.2 . In children, a small atrial systolic flow reversal of short duration is often present (62,106). The pulmonary venous A-wave velocity is 21 ± 5 cm/s with duration of approximately 130 ± 20 ms (102).

TDI assessment of mitral annular velocities (Fig. 9.28) in the normal LV shows an E'-wave/A'-wave velocity ratio >1. Relaxation of the ventricle produces movement of the mitral valve annulus away from the transducer in the apical four-chamber view; atrial systole produces a mitral annular A' wave, reflecting the motion of the mitral annulus away from the transducer with late systolic ventricular filling. Normal values for both mitral and tricuspid annular velocities in children have been published (65,68,107).

ABNORMALITIES OF LEFT VENTRICULAR DIASTOLIC FUNCTION

Stage I Diastolic Dysfunction: Impaired Relaxation

In the earliest stages of diastolic dysfunction, the rate of ventricular relaxation is impaired. Delayed LV relaxation results in a slower decline in LV pressure resulting in a diminished gradient between the left atrium and LV in early diastole and a diminished mitral E-wave velocity. The slow relaxation also results in a lengthening of the IVRT and E-wave deceleration time. As a result, there is a compensatory increase in late filling during atrial systole, producing an augmented mitral A wave. These changes occur when ventricular compliance and LA and LV end-diastolic pressures are at near normal levels.

In the pulmonary veins, delayed relaxation results in reduced early diastolic flow, resulting in an augmented systolic S wave and a diminished D wave. This results in an increased S/D-wave velocity ratio. This index should be interpreted with caution in children as many normal children have higher S than D waves in the pulmonary veins. As atrial pressures are near normal at this stage of dysfunction, atrial systolic flow reversal remains absent or small (Fig. 9.34). TDI of the lateral mitral annular velocities will demonstrate a decrease in the peak E' velocity, corresponding to decrease in early diastolic ventricular relaxation. The E'/A' velocity ratio will therefore be <1 in this setting (Fig. 9.35).

Stage II: Pseudonormal Diastolic Dysfunction

Diastolic function indices in stage II dysfunction are summarized in Figure 9.35. As diastolic dysfunction advances,

Figure 9.34. Physiologic left ventricle (LV)/left atrial pressure relation with normal diastolic function and two stages of diastolic dysfunction. A: Normal ventricular relation produces a normal rise in the pressure gradient between the left atrium and LV at the conclusion of isovolumic relaxation. This results in a normal mitral E wave. Normal atrial contraction at end-diastole produces a normal mitral A wave. B: Impaired relaxation prolongs the IVRT and results in a diminished pressure gradient between the left atrium and LV in early diastole. This results in a diminished mitral E wave, with a compensatory increase in the mitral A wave during atrial systole. C: Rising left atrial pressure restores the early diastolic gradient between the left atrium and LV, resulting in a pseudonormal E-wave velocity. LAP, left atrial pressure.

Figure 9.35. Progression from normal diastolic function (A) to early (B,C) and advanced (D) phases of diastolic dysfunction with demonstration of the associated changes in the mitral inflow, pulmonary venous flow, and mitral annular Doppler tissue imaging indices. TDI, Tissue Doppler Imaging; PV, pulmonary venous.

ventricular compliance progressively diminishes along with continued abnormalities in ventricular relaxation. Ventricular filling becomes dependent on a compensatory increase in LA pressure. The increase in LA pressure has several effects: an increase in the left atrium to LV pressure gradient in early diastole produces an increase in the mitral E-wave velocity and a shortening of the IVRT by producing early mitral valve opening. Progressive decreases in ventricular compliance result in shortening of the E-wave deceleration time. These changes lead to so-called pseudonormalization of the mitral inflow Doppler pattern. Although tissue Doppler, deformation imaging, and color M-mode help differentiate pseudonormal from normal, inspection of the M-mode, 2-D echo, and mitral inflow Doppler themselves can be useful to differentiate normal from pseudonormal. A heart with vigorous left and right ventricular contraction, normal wall thickness, and normal left and right ventricular and atrial sizes is most likely normal. A normal-sized but “hypercontractile” appearing left atrium, with increased annular excursion toward the pulmonary veins suggests reduced early diastolic LV filling and impaired ventricular relaxation. Likewise, in pseudonormalization, although the E/A ratio appears normal, the E wave is often higher than normal (due to the elevated atrial pressure), and higher than the LV outflow velocity. Finally, the Valsalva maneuver that impairs LA filling, thereby reducing the E wave velocity, can be used to unmask delayed relaxation when a pseudonormal pattern is present.

The pulmonary venous flow profile features a decrement in the magnitude of the S wave and an increase in the D wave, resulting in a diminished S-/D-wave velocity ratio. The pulmonary venous A-wave velocity and duration will increase as ventricular compliance worsens. In adult studies, pulmonary venous A-wave velocities of >35 cm/s or pulmonary venous A-wave durations that exceed the mitral A-wave duration by ≥ 30 ms have been reported to distinguish normal mitral inflow profiles from pseudonormal mitral inflow profiles (61,108). In the pediatric population, the difference between pulmonary venous A-wave duration and mitral A-wave duration can identify children with elevated LV filling pressures. However, these methods are adequately predictive only when the LV end-diastolic pressures are >18 mm Hg (62).

The pattern of mitral annular velocities remains largely unchanged in the setting of pseudonormal dysfunction. Abnormal relaxation will again result in a diminished E'

velocity and an E'/A' velocity ratio of <1 . Thus, TDI can be useful to distinguish normal from pseudonormal mitral valve inflow profiles (69,109). This is particularly true when obtaining technically adequate pulmonary venous A-wave profiles on transthoracic echocardiography proves difficult, or when LA pressure is modestly elevated. An additional index of diastolic function that has been correlated to elevations in ventricular filling pressures is the ratio of transmitral E wave to lateral mitral annular velocity (or the average of the lateral and septal velocities)—the E/E' ratio. This ratio was found to correlate with pulmonary capillary wedge pressures in the presence of delayed relaxation (110,111). However, in one study, the E/E' ratio did not successfully predict elevated pulmonary capillary wedge pressures in adults with decompensated advanced heart failure (112). In light of these findings, further validation is required in children to assess the usefulness of the E/E' ratio in specific conditions. The relation between the onset of mitral filling to the onset of mitral annular tissue motion can also be used to assess LA pressures and differentiate pseudonormal from normal. In the normal heart, there is vigorous relaxation with suction of blood early in diastole. Therefore, the E' wave will appear slightly earlier or simultaneously with the mitral E inflow. In the presence of impaired ventricular relaxation and with increased atrial pressure driving filling, the E wave will precede the tissue E' wave.

Stage III Diastolic Dysfunction: Restrictive Physiology

As diastolic dysfunction worsens, a restrictive pattern emerges. The changes on Doppler parameters are summarized in Figure 9.35. LA pressure and LV stiffness are very high. The increase in LA pressure results in rapid inflow of blood into the LV during early diastole, producing a tall E wave. However, low LV compliance causes premature termination of early ventricular filling with narrowing of the E wave and further shortening of the E-wave deceleration. Likewise, due to the low compliance, filling in late diastole is reduced resulting in a small A wave. Transmitral Doppler findings therefore feature an increased E-/A-wave ratio, typically >2 , and further shortening of the E-wave deceleration time, which is typically <150 ms in adult studies (108) and shorter still in children. Of note, severe restrictive physiology results in a rapid rise in intraventricular pressures during diastolic filling, which will occasionally produce diastolic mitral regurgitation, especially

when the AV conduction delay is prolonged. These findings can be appreciated on color flow-Doppler imaging (113,114).

In the pulmonary veins, there is further worsening of the trend seen in pseudonormal dysfunction, with further decreases in the fraction of systolic pulmonary venous flow and further increases in the diastolic fraction, resulting in further reduction in the S-/D-wave velocity ratio. The magnitude and duration of the atrial systolic reversal frequently becomes quite pronounced.

TDI in restrictive physiology will demonstrate decreased E' velocities (58,109). Overall, the magnitude of annular velocities—both E' and A' waves—is low, given the combined effects of severely decreased relaxation and compliance. The E/E' ratio will be higher than in preceding stages of dysfunction.

A further, more severe stage of restrictive physiology is proposed in the adult literature (stage 4). This stage is characterized by similar or worse parameters than stage 3, but a negative response to the Valsalva maneuver, indicating irreversible disease.

Difficulties in Distinguishing Normal from Abnormal Diastolic Function in Children

Throughout this section we have discussed differences between adults and children and difficulties, especially in children, in interpreting diastolic function. Patterns and values considered abnormal in adults are often found in normal children. In addition, parameters are affected by age, heart size, heart rate, variable loading conditions, the heterogeneity of congenital heart disease, and whether the disease process is acute or chronic, compensated, or decompensated. Although normal pediatric reference data are available, there is a wide range of normal values reported in the literature. This pertains both to Doppler-flow parameters, TDI parameters, and deformation parameters (62,64). Furthermore, large areas of overlap in many indices have been found between normal children and those with increased filling pressures (62). Lack of validation of adult paradigms and correlation of abnormal echo-diastolic parameters compared with invasive reference methods in various diseases are additional limitations.

Constrictive Pericarditis

Constrictive pericarditis, although uncommon in children, can manifest very similar diastolic findings to restrictive physiology. The transmitral flow pattern can be very similar and feature an increased E-/A-wave ratio and a shortened E-wave deceleration time. Several findings can help distinguish constrictive pericarditis from restrictive cardiomyopathy. In constrictive pericarditis, simultaneous respirometry will reveal increased variation in the mitral valve E-wave velocities (>25%) and augmentation of pulmonary venous flows during respiration, that are not seen with restrictive physiology (115). In addition, Doppler assessment of the hepatic venous flow will show increased atrial systolic flow reversal during expiration with constriction and during inspiration with restrictive physiology (116). TDI in constrictive pericarditis will show a normal E' velocity in constriction, where the myocardium is relatively normal, compared with a low E' velocity in the diseased muscle of restrictive physiology (109). It is important to remember that in constrictive pericarditis, there may be a normal E/E' ratio despite elevated filling pressures due to the normal E' velocity (117). It should also be noted that the aforementioned findings have not been validated in pediatric studies of constrictive and restrictive physiology.

Assessment of Diastolic Function During Exercise

The ability of the heart to increase its relaxation and suction effect in response to the increased cardiac output during exercise, at a time when diastole is significantly shortened, is

a key component of cardiac physiology. Therefore, assessment of diastolic function and diastolic reserve during the provocative physiology of exercise may be valuable (118). In response to exercise, untwisting of the heart is augmented allowing rapid filling in a shorter time period (96). This augmentation is closely linked to increased systolic twisting demonstrated by speckle tracking (97,119). Although multiple diastolic parameters can be assessed, the E/E' ratio is commonly used. Abnormal hearts will demonstrate relative worsening of relaxation with decreased E' velocities and an increased E/E' ratio. Studies in children are limited.

Doppler Assessment of Right Ventricular Diastolic Function

Diastolic dysfunction of the RV (either in a systemic or pulmonary position or as a single ventricle) can also be assessed by Doppler techniques. However, it is less clear what specific findings are representative of normal baseline ventricular diastolic function in these instances. There has been work describing diastolic dysfunction, for example, in the single ventricle (100,111), but it is likely that diastolic dysfunction will need to be stratified for severity within a specific diagnosis. Moreover, variations of flow patterns with respiration are prevalent on the right side of the heart; therefore, diastolic findings will need interpretation in view of their phase of respiration.

Diastolic function of the RV can be assessed by assessment of transtricuspid Doppler flow patterns, TDI of the lateral tricuspid annulus, and assessment of the systemic venous inflow. Unlike the LV, however, in which echocardiographic diastolic indices have been validated in large adult populations, assessment of RV diastolic dysfunction in children has historically been confined to assessment in several fairly heterogeneous circumstances such as, postoperative TOF (120–122), systemic RVs, and single RV physiology (123,124). As such, normal diastolic function is difficult to define in these circumstances, and diastolic findings are often compared within a specific population against other clinical parameters. In addition, the Doppler profile of tricuspid inflow is often less sharp than that of mitral inflow, making precise and reproducible measurements more difficult. Nonetheless, published normal values for both tricuspid inflow Doppler flow profiles (65,125,126) and tricuspid annular velocities (65,127) exist for the pediatric population, and can be used to evaluate RV diastolic function in the same way as one would assess diastolic function of the LV. Both systemic venous and transtricuspid flow can vary significantly during respiration (125); diastolic assessments of the RV and systemic venous inflow should therefore be standardized for phase of respiration using simultaneous respirometry. Respirometry can be particularly helpful in assessing systemic venous flow patterns, as these can often be important in distinguishing restrictive diastolic physiology from a more constrictive pattern as described above. Pulsed-wave Doppler assessment of flow in the proximal pulmonary artery is also useful when RV diastolic dysfunction is suspected, as antegrade flow in the main pulmonary artery during atrial systole that occurs in both inspiration and expiration, has been associated with restrictive RV physiology in postoperative TOF (Fig. 9.36) (121,127). RA dilation in the absence of tricuspid regurgitation could be considered as an important parameter for RV diastolic dysfunction but in contrast to the left atrium, no good normal values are present for the pediatric age range and no good method has been developed for measuring RA volumes. RA area can be measured. Flow in the hepatic veins should also be recorded. Significant flow reversal in the hepatic veins during atrial contraction is a sign of elevated RV end-diastolic pressure but no specific cutoff values have been provided (Fig. 9.37).

Figure 9.36. Restrictive RV physiology in a patient after tetralogy of Fallot repair. Pulsed-wave Doppler tracing obtained at the level of the pulmonary valve. This patient had severe pulmonary regurgitation as indicated by the short pressure half-time and only early diastolic flow reversal. During atrial contraction antegrade flow across the pulmonary valve can be recorded (arrows). This suggests that RV end-diastolic pressure during atrial contraction exceeds pulmonary diastolic pressure, which is consistent with restrictive RV physiology.

Figure 9.37. Pulsed Doppler sampled in the hepatic vein of a patient with hypertrophic cardiomyopathy. Respirometry is seen in green. Findings are consistent with restrictive features with systolic antegrade flow (asterisks), retrograde flow in early diastole (arrowheads), and marked flow reversal after atrial contraction (arrows). In this patient these abnormalities are present during inspiration and expiration.

EVALUATION OF VENTRICULAR SYNCHRONY

Normal cardiac activation and contraction is rapid and homogeneous with coordinated contraction of the atria to fill the ventricles at end-diastole, homogenous contraction between the different segments of the systemic ventricle, and the activation of the left and RVs within 50 to 80 ms (129). Dyssynchrony refers to the incoordinate or heterogeneous activation and contraction of the cardiac chambers, especially the ventricles. Electrical dyssynchrony refers to slow and inhomogeneous activation of the ventricles and is most commonly measured using the QRS duration from the surface electrocardiogram. Mechanical dyssynchrony refers to the heterogeneous contraction of the cardiac chambers and is most commonly and easily measured using echocardiography. With the increasing evidence and recognition that ventricular dyssynchrony is a risk factor for ventricular dysfunction and increased morbidity and mortality in patients with heart failure (130,131), and with the advent of cardiac resynchronization therapy (CRT) using biventricular or multisite pacing to treat ventricular dyssynchrony (132,133), it has become important to diagnose dyssynchrony, identify likely responders to CRT, and to optimize pacemaker settings after implantation (134,135). Some studies have suggested that echo may be useful to guide the optimal site of lead placement during pacemaker implantation for CRT (136,137). Three levels of dyssynchrony are generally identified: (a) atrioventricular dyssynchrony—the timing between atrial systole and ventricular diastole, (b) interventricular dyssynchrony—incoordinate contraction between the left and RVs, and (c) intraventricular dyssynchrony—incoordinate contraction between different segments of the LV or RV.

QRS duration is the most widely accepted criteria to diagnose ventricular dyssynchrony for the purposes of predicting response to CRT (138,139). However, approximately one-third of adult patients do not respond to CRT based on standard criteria using QRS duration (140). One assumption was that these patients may not have mechanical dyssynchrony and therefore did not respond to CRT or conversely that ECG might not be sensitive enough to detect the presence of regional abnormalities arising from distal conduction disease not reflected in the QRS duration. Therefore, echo criteria to determine mechanical dyssynchrony, especially LV intraventricular dyssynchrony,

have been investigated in the hope of better identifying patients who may respond to CRT. Early trials based on single-center experiences and largely based on TDI of mechanical dyssynchrony showed that echo could identify patients likely to respond to CRT better than QRS duration alone (141–145). Unfortunately, this experience was not confirmed in a large prospective randomized multicenter trial (PROSPECT) using either clinical improvement or a decrease in ventricular volumes (reverse remodeling) as outcomes (146). Likewise, echo criteria of mechanical dyssynchrony failed to predict response to CRT in heart failure patients with a narrow QRS duration using an increase in peak oxygen consumption during exercise as the outcome (147). These trials have left the field with much uncertainty as to the role of echo in assessment of dyssynchrony and in choosing candidates for CRT. Currently, echo criteria are not recommended to implement or withhold CRT from a patient (148). Nonetheless, many authors believe that mechanical dyssynchrony is an important component of ventricular dysfunction, that CRT addresses this phenomenon, and that echo holds the greatest potential to measure mechanical dyssynchrony given its high spatial and temporal resolution, its availability, and the ability for serial measurements, especially in patients with an implanted pacemaker, which is currently a relative contraindication to MRI (135,149,150). Some authors have advocated for using a more broad-based echocardiographic approach, assessing atrioventricular, intraventricular, and interventricular dyssynchrony as possible discrete mechanisms that may be present in different patients, thereby tailoring CRT to the underlying type of dyssynchrony (151). The question remains what is the best way to evaluate abnormal electromechanical coupling, measure mechanical dyssynchrony, and what is the ability of any given method to predict response to CRT? Currently there is no simple or single answer to these questions. The field continues to evolve, and multiple echo indices to measure mechanical dyssynchrony have been published. In children, answers are far more vague with limited data and there are no published values to predict response to CRT.

In the following section, we will summarize the main echo indices and modalities currently used to measure mechanical dyssynchrony. Many other dyssynchrony indices have been investigated but are beyond the scope of this text.

ECHOCARDIOGRAPHIC ASSESSMENT OF THE ATRIOVENTRICULAR DELAY

Assessment of the AV delay is most commonly assessed after CRT implantation when optimizing device settings. This assessment is not necessary in every patient (148). Although several methods are available, AV dyssynchrony is most easily measured using pulsed Doppler of the mitral inflow by the iterative method (visual assessment). Optimal filling occurs when the systemic inflow E and A waves are clearly identified and separated from one another. The end of the A wave should be aligned with the QRS complex and/or mitral valve click (148).

ASSESSMENT OF INTERVENTRICULAR DYSSYNCHRONY

The interventricular delay is measured as the delay between the onset of LV and RV ejection (Fig. 9.38). This is most easily measured from the onset of ECG Q wave to the onset of pulsed Doppler flow in the LV and RV outflow tracts or proximal aorta and pulmonary artery (148). Although this index

has not traditionally been used to predict response to CRT, it is one of the most reliably measured indices, may identify adults with increased response to CRT, and may be important in children with congenital heart disease (152,153).

ASSESSMENT OF INTRAVENTRICULAR DYSSYNCHRONY

To date, echo assessment of mechanical dyssynchrony has largely focused on assessment of intraventricular dyssynchrony as this parameter is thought to be most predictive of CRT in adults.

M-mode

The most common M-mode dyssynchrony index is the septal-posterior wall delay measured from peak excursion of the septum to peak excursion of the posterior wall. A delay of more than 130 ms is considered abnormal in adults (154). Assessment of a very limited segment of the heart, difficulties in identifying the peak excursion when wall motion is flat as is commonly seen in ventricular dysfunction, and motion arising from tethering of the interrogated segment to adjacent segments limits the utility of this index. In the presence of left bundle branch block, a sharp thinning-thickening (or lengthening-shortening) motion of the septum in the preejection period (termed the “septal flash”), which can be demonstrated by M-mode or by tissue-Doppler imaging, has been found by one group to have a high specificity for response to CRT in adults as judged by reverse LV remodeling (151).

Tissue Doppler Imaging

To date, TDI, usually by color TDI with off-line analysis, has been the most common method to assess mechanical intraventricular dyssynchrony. TDI indices can be measured at any point of the ventricular myocardium to give information on regional wall motion. Because of this feature, TDI indices are not only useful in the assessment of ventricular function, but may be valuable in assessing ventricular dyssynchrony and response to CRT (155). Multiple TDI dyssynchrony indices based on TDI have been published. These generally measure the time to onset or peak systolic motion in a varying number of LV segments using the QRS complex as a reference. One of the most commonly used indices calculates the time-to-peak systolic motion (during ejection) in 12 LV basal and mid segments, assessed from the apical four-, three-, and two-chamber views, and expresses the heterogeneity of longitudinal motion as a standard deviation (Fig. 9.39) (156,157). Other indices measure the difference in time-to-peak systolic longitudinal motion between 2, 4, or 12 LV segments (143,148). However, indices based on the measurement of a single-tissue velocity point, which is often variable and difficult to identify, tend to have poor intra- and interobserver reliability (146). A promising approach integrates multiple points along the LV velocity curve essentially analyzing the motion of the wall throughout the systole. The relative delay between the two segments of interest (the shift in curves) can then be calculated using cross-correlation computation (158). This computation is not yet routinely available on common commercial ultrasound analysis platforms. The major advantage of TDI for mechanical dyssynchrony analysis is the ability to easily and quickly obtain data from multiple segments simultaneously (in the same cardiac cycle) at high frame rates. Major disadvantages include difficulties in identifying peak systolic motion when multiple

Figure 9.38. The interventricular delay represents the delay in ejection between the left ventricle (LV) and the right ventricle (RV). This is calculated as the time difference between the onset on QRS complex as the reference (*first white line*) and the onset of pulmonary (RVOT, *top panel*) and aortic (LVOT, *bottom panel*) ejection, respectively. In this example there is a 66 msec delay between onset of ejection of the RV and subsequently the LV (*second white line*), which is prolonged. It is important to acquire the samples at the same heart rate. In this example there is a small difference in heart rate between the two images (<10%). The measurement cannot be used when heart rate is significantly different at time of sampling.

Figure 9.39. Assessment of left ventricular (LV) intraventricular dyssynchrony using tissue Doppler to measure the left ventricular dyssynchrony (Yu) index. Aortic valve opening and closing are marked by the *green lines* to delineate ventricular ejection. In **panel A** 12 tissue Doppler curves are obtained from the basal and mid regions from apical 4 (top), 2 (middle), and 3 (bottom) chamber views. The time to peak velocity is measured using the onset of the QRS complex as a reference point. The standard deviation of the time to peak velocity during ejection is measured as the dyssynchrony index. In this normal example, tissue velocities reach their peak nearly simultaneously so that the standard deviation of time to peak velocity curves is low. In contrast, **panel B** shows curves from a patient with dilated cardiomyopathy where different segments reach peak velocity at different times. This would increase the standard deviation of time to peak velocity and indicate LV intraventricular dyssynchrony. For the sake of clarity, only 6 of the 12 segments sampled are shown.

peaks are present or when a clear peak is not visible. Wall motion profiles may differ between segments complicating analysis. These factors lead to poor reproducibility. Moreover, motion of the interrogated segment may be passive due to translation of the entire heart or due to tethering of a noncontractile segment to adjacent segments. The importance of tethering in children, who generally do not have discrete regions of infarcted myocardium except in very specific circumstances, is unknown.

Deformation Imaging

Because of the poor results predicting response to CRT using tissue Doppler techniques and because of its high intra- and interobserver reliability, echo measurement of dyssynchrony using deformation imaging is increasing (159,160). One method measures the delay between time-to-peak radial strain between the septum and posterior wall (similar to the M-mode technique) at mid-ventricular level with a 130 ms cutoff quoted in the adult literature (Fig. 9.40) (161). Adding the radial septal to posterior wall delay to longitudinal assessment by TDI may increase the ability of echo to predict response to CRT (162). Other authors have used the delay between time-to-peak longitudinal strain in the septum and lateral wall. By measuring active contraction, strain imaging overcomes the problem of passive translational motion and tethering. However, the utility of deformation imaging to predict the response to CRT in large populations and in multicenter setting needs validation. Other disadvantages include a lower frame rate

than tissue Doppler (for speckle tracking), lack of standardization for which segments to measure and as for TDI measurements, how large the region of interest should be (163), and relatively poor reproducibility. Despite the theoretical benefits of deformation imaging, our practical experience has been that it is difficult to obtain reliable strain curves for dyssynchrony measurements in a substantial proportion of children with ventricular dysfunction.

Three-Dimensional Echocardiography

LV dyssynchrony can be readily measured by 3-D echo in adults and children (164,165). The full LV 3-D volume is segmented by postprocessing software into subvolumes around the LV central meridional axis. The standard deviation of time to minimal volume between 12 and 16 subvolumes is then used as a dyssynchrony index (Fig. 9.41). To account for different heart rates, the dyssynchrony index can be expressed as a percentage of the cardiac cycle length. Disadvantages of 3-D echo are the low frame rates and the indirect assessment of wall motion through assessment of volume change.

Assessment of Mechanical Dyssynchrony in Children

Dyssynchrony has been shown to be important in children and adolescents in a number of acquired and congenital conditions. Data on RV and LV dyssynchrony by various modalities

Figure 9.40. Radial strain curves obtained in six segments from a mid parasternal short-axis cut. Note that peak systolic strain occurs nearly simultaneously in the six measured segments.

derived from normal populations are emerging but are still limited (166–168). More importantly, to date, there are no data pertaining to mechanical dyssynchrony cut-points that may predict response to CRT in children. Likewise, the largest published CRT experience in children has not described mechanical dyssynchrony (169–171). Most studies have largely been restricted to investigating the prevalence of dyssynchrony in various conditions and investigating its impact on cardiac function, exercise capacity, and clinical outcomes. In children with dilated cardiomyopathy, and in normal controls, the degree of radial deformation (which is related to contractility) was found

to be related to the time it took to develop peak deformation, thereby providing a direct link between timing of contraction and regional function (172). Indeed, systolic dyssynchrony measured by TDI and by strain is prevalent in children with dilated cardiomyopathy, even when the QRS duration is narrow (173,174). Mechanical dyssynchrony was not significantly linked to death or transplant in a relatively small study using TDI assessment (175), although by 3-D assessment, it has been linked to LV EF (165). Diastolic dyssynchrony has also been found to be prevalent in this population and is possibly linked to increased risk for death or transplant (176).

Figure 9.41. Three-dimensional synchrony. Three-dimensional left ventricular (LV) full volume. After tracing the endocardial borders, a LV volume is generated and tracked over the cardiac cycle. The post-processing software generates 17 subvolumes around the meridional axis. The change in each subvolume over the cardiac cycle is represented in the curves at the bottom of the figure. In this example, all subvolumes reach minimal volume at approximately the same time (*arrow*) depicting synchronous LV contraction.

Dyssynchrony, demonstrated by echo, is also important in children with congenital heart disease. RV wall motion abnormalities are commonly found after repair of TOF and in the systemic RV after atrial switch procedures where pulsed tissue-Doppler has demonstrated opposing longitudinal motion in the RV free wall (177,178). These abnormalities were related to electrical activation (QRS duration) and risk for arrhythmia. Indeed, after surgical repair of TOF, where right bundle branch block is common, electromechanical interactions seem to be important, especially when involving the infundibulum as shown by pulsed tissue Doppler, M-mode, and deformation imaging (179,180). These wall abnormalities may also impact TOF patients' responses to exercise. During exercise, even asymptomatic TOF patients develop both RV and LV dyssynchrony as shown by TDI (181). Likewise an increased interventricular delay has been linked with decreased exercise capacity and increased risk for ventricular arrhythmias during exercise (153). Wall motion abnormalities impacting ventricular function have also been found in the LV in TOF patients, where an increased delay between time-to-peak deformation between the lateral wall and septum has been associated with decreased global LV function (178). LV dyssynchrony and dysfunction in congenital disease affecting the RV may stem from adverse ventricular-ventricular interactions (182–185) as LV dyssynchrony was more prevalent in the presence of abnormal septal motion, more pulmonary regurgitation, larger RV volumes, and right bundle branch block (182,185). RV mechanical dyssynchrony has been demonstrated using vector velocity imaging, a form of deformation imaging, in children with hypoplastic left heart syndrome (186). The amount of dyssynchrony differed between different stages of palliation. Whether this dyssynchrony constitutes a marker for later development of ventricular dysfunction in this population, is unknown. However, in the failing systemic RV, mechanical dyssynchrony may be an important component of the response to CRT (187). Acutely after surgery, biventricular pacing is likely superior to single-site pacing in terms of wall motion and hemodynamics, as assessed by TDI (155). Indeed, increased mechanical dyssynchrony by tissue Doppler and strain imaging may be associated with decreased cardiac output after congenital heart disease surgery, and this may respond to biventricular pacing.

CORONARY ARTERY PHYSIOLOGY

Coronary artery physiology and pathology play an important role in congenital conditions, and assessment of coronary artery physiology is gaining an increasingly important role for the pediatric and congenital echocardiographer. In children, coronary artery abnormalities are predominantly related to (a) an abnormal origin or course (e.g., left coronary artery arising from the right facing sinus), (b) inflammatory diseases (e.g., Kawasaki disease), (c) problems related to surgical reimplantation (e.g., repair of anomalous left coronary artery from the pulmonary artery, arterial switch procedure, pulmonary autograft (Ross) procedure), (d) early atherosclerosis, (e) reduced flow related to high end-diastolic pressure (e.g., LV outflow tract obstruction, cardiomyopathy), and (f) compression of the coronary arteries (e.g., myocardial bridging in hypertrophic cardiomyopathy). The specific etiology in question will influence the type and extent of imaging performed. Two-dimensional and color flow echocardiography are useful for imaging coronary artery origins, course, aneurysms, and dilatation, but are less useful for detecting coronary artery stenosis, aside from perhaps coronary ostial stenosis.

Coronary echocardiography or ultrasound can be divided into the following broad categories:

1. Direct imaging of the coronary arteries
2. Assessment of regional myocardial function at rest and during stress that may indicate perfusion abnormalities in specific myocardial territories
3. Vascular imaging to detect early atherosclerosis

In this section, we refer to general imaging of coronary artery physiology. Specific abnormalities are covered in the respective chapters.

Coronary physiology can be assessed by studying peripheral arterial structure and function or by direct interrogation of the coronary arteries themselves.

The peripheral arteries serve as surrogate windows for the study of coronary artery physiology. Carotid intima-medial thickness is a precursor of atherosclerosis (188,189) and can be measured by high-frequency ultrasound (15 MHz).

Peripheral arterial endothelial function is assessed by brachial artery flow-mediated dilation. This technique involves inflating a sphygmomanometer cuff placed on the forearm or upper arm to a pressure of 100 to 150 mm Hg above the systolic pressure for 4 to 5 minutes. The brachial artery diameter immediately after cuff deflation is compared with the baseline diameter before inflation. The technique produces very subtle changes and must be performed in a highly controlled environment free of extraneous influences. Both carotid intima-medial thickness and brachial artery flow-mediated dilation have been used successfully to show impairment of vascular function, and therefore, presumably coronary arterial function in children with insulin-dependent diabetes mellitus (190,191). Vascular function can also be assessed by applanation tonometry, a nonultrasound technique that necessitates noninvasive capture of a large artery waveform using high-fidelity transducers and from which cardiovascular risk can be assessed (192).

Direct Assessment of the Coronary Arteries

Two-dimensional and color-flow imaging of the coronary arteries can show anomalous origins, abnormal branching patterns and courses of the coronary arteries, coronary aneurysms and/ or dilation, and coronary fistulae. Direct assessment of the coronary arteries is still limited and a coronary abnormality should be considered when other signs of myocardial ischemia or infarction are present, such as global or regional ventricular dysfunction, ventricular and atrial enlargement, the presence of mitral regurgitation, echogenic papillary muscles or myocardium, and flow reversal in the left anterior descending artery by color flow Doppler in anomalous origin of the left coronary artery from the pulmonary artery.

Direct functional assessment of the coronary arteries largely rests on Doppler assessment of coronary flow although it is not routinely performed in most pediatric clinical institutions. Nonetheless, Doppler flow velocities have been found to correlate well with invasive measurements by Doppler guide wire in adults and in pediatric studies, albeit in a small number of subjects (193–195). Normal values for Doppler flow velocities at rest in the left coronary artery have been published in a cohort of over 300 children (196), and have been studied in the branch coronary arteries (197). Velocities, which ranged up to 60 cm/s in young children, decreased with age and increased with heart rate.

Coronary flow reserve reflects the increase in coronary flow in response to stimuli such as pharmacologic agents

(e.g., adenosine triphosphate, and dipyridamole) and exercise. It is calculated as the ratio of the peak (or mean) diastolic velocity after hyperemic stimulation to the baseline peak (or mean) diastolic velocity and reflects the resistance of the coronary bed, its ability to maintain constant flow when myocardial perfusion pressure changes (autoregulation), and the ability to augment blood flow in response to stress (198). Coronary flow reserve is affected not only by stenosis or compression of the proximal coronary arteries, such as in Kawasaki disease (195,199) or hypertrophic cardiomyopathy (200), but also by abnormalities in the distal coronary microvasculature such as in dilated cardiomyopathy, where decreased coronary flow reserve by Doppler echo has been linked to worse outcome (201,202). More reassuringly, normal coronary flow reserve has been found in a small study of children after arterial switch operation for transposition of the great arteries, although a number of children with variant left coronary anomaly demonstrated abnormal coronary flow reserve by cardiac positron emission tomographic imaging in response to adenosine (203). These normal findings in most children after the arterial switch operation mirror an invasive study using a Doppler guidewire and (204) may predict lower risk for atherosclerosis in the following decade (205). On the other hand, past publications have found that while coronary artery anatomy is not a determinant of outcome after the arterial switch operation, a portion of children may have silent ischemia without echocardiographic abnormalities at rest (206). Whether these children will demonstrate abnormal coronary flow reserve is unknown. Echo Doppler assessment of coronary flow reserve in the right coronary artery has also been shown to be feasible in an adult population, using a coronary Doppler flow wire as a reference (203).

Given the important limitations of echocardiography in detecting coronary anomalies, especially those related to coronary stenosis and perfusion abnormalities, there should be a low threshold to proceed to other imaging modalities when there is a clinical suspicion of coronary stenosis or a perfusion abnormality. Alternative imaging modalities for this indication include computerized tomography, cardiac MRI, nuclear imaging, and especially coronary angiography, which remains the reference standard.

Coronary Perfusion

One of the major uses of stress echocardiography is in the assessment of coronary perfusion (204). Myocardial ischemia develops when myocardial oxygen demand exceeds supply. Ischemia can manifest by angina (a relatively late manifestation evident by patient history), a metabolic abnormality (a relatively early manifestation evident by positron emission tomography), or several intermediate manifestations such as ST-segment depression on the electrocardiogram or poor radioisotope perfusion on a thallium scan. On the echocardiogram, ischemia is manifested by a new or worsening regional wall motion abnormality. In children, stress echocardiography for coronary assessment can be useful for a variety of indications including Kawasaki disease, detection of coronary artery vasculopathy in the transplanted heart (205,206), and after the arterial switch operation. In children, although an abnormal DSE correlates relatively well with angiographic abnormalities in the coronary vessels (206), one of the main problems is the low pretest probability of an abnormality resulting in a low positive predictive value of the exam. It is currently our institutional practice to limit routine dobutamine stress echocardiography for detection of transplant vasculopathy to patients who are more than 3 years after transplant and who have risk factors for rejection or previous rejection.

Since publication of the previous edition of this textbook, the field of cardiovascular magnetic resonance imaging (CMR) has continued to experience rapid evolution in technology and clinical applications. During the past decade, developments in hardware design, computer sciences, and imaging sequences have led to a marked expansion of the clinical utility of CMR in patients with congenital and acquired pediatric heart disease. CMR is rarely used as the first or the sole diagnostic imaging test. It complements echocardiography, provides a noninvasive alternative to x-ray angiography, and overcomes many of the limitations of these modalities. For example, in contrast to echocardiography, acoustic windows and body size do not limit CMR, and, unlike cardiac catheterization, CMR does not use ionizing radiation. In today's clinical practice, CMR is increasingly used in concert with other imaging modalities (most commonly echocardiography) for assessment of cardiac anatomy and function, measurements of blood flow, tissue characterization, and, more recently, evaluation of myocardial perfusion and viability. This chapter reviews common CMR techniques and discusses the clinical applications of CMR in patients with congenital and acquired pediatric heart disease.

INDICATION FOR MAGNETIC RESONANCE IMAGING EVALUATION OF CONGENITAL HEART DISEASE

The indications for CMR in patients with congenital heart disease (CHD) continue to expand. Given that CMR has been shown to provide helpful diagnostic information in most types of CHD, it is not practical to list individual anomalies in which the test is indicated. In general, the clinical reasons for a CMR examination fall into one or more of the following categories:

1. When transthoracic echocardiography cannot provide the required diagnostic information
2. When clinical assessment and other diagnostic tests are inconsistent
3. As an alternative to diagnostic cardiac catheterization with its associated risks and higher cost
4. To obtain diagnostic information for which CMR offers unique advantages

In clinical practice, CMR is typically ordered after other imaging studies have been performed and additional diagnostic information is required. Table 10.1 summarizes the primary referral diagnoses in 1,334 consecutive CMR examinations performed in 1,183 patients at Children's Hospital Boston in 2003 to 2004 (1), illustrating the wide range of cardiovascular anomalies evaluated.

It is worth noting that the role of CMR in infants and toddlers is more limited than that in older patients.

Because poor acoustic windows are less common in infants, echocardiography can provide the necessary diagnostic information in most patients, and CMR under sedation or anesthesia is reserved for those in whom additional information is necessary. A review of 99 consecutive CMR examinations in patients younger than 1 year of age during a 4-year period (January 1999 through December 2002) at Children's Hospital Boston found that delineation of the thoracic vasculature was the most common indication (55%), followed by assessment of airways compression (25%) and evaluation of cardiac tumors (6%) (272). In the future, CMR will likely assume a greater role in this age group, primarily as an alternative to diagnostic cardiac catheterization. Examples of such scenarios include delineation of sources of pulmonary blood supply in tetralogy of Fallot (TOF) with pulmonary atresia and preoperative assessment of candidates for a bidirectional Glenn shunt.

MAGNETIC RESONANCE IMAGING TECHNIQUES

Background

In magnetic resonance imaging (MRI), magnetic fields and radiofrequency (RF) energy are used to stimulate nuclei in selected regions of the body to emit radio waves that are then processed to construct images. The primary source of signals used to construct MR images is derived from hydrogen protons (^1H). The ^1H protons can be thought of as tiny bar magnets that, when placed in a strong magnetic field, will align and precess (rotate) around the axis of the magnetic field. The highest concentrations of ^1H protons are in water and fat. Through the use of a strong static magnetic field, much weaker but rapidly varying magnetic field gradients, and short pulses of RF energy, the ^1H protons (also referred to as *spins*) in selected regions of the body are stimulated to emit RF waves. These RF waves are then used to construct MR images (Fig. 10.1). The strength of the static magnetic field in most clinical scanners used for CMR is either 1.5 or 3.0 Tesla (T) (1 Tesla = 10,000 gauss [G]; the strength of earth's magnetic field at its surface is ~0.5 G).

As with any other diagnostic modality, an in-depth knowledge of underlying MRI physics is essential for maximizing its utility and understanding its pitfalls and limitations. This, in turn, enhances the quality of the interpretation of the imaging data. A detailed discussion of MRI physics is beyond the scope of this chapter and can be found in other sources (2,3). Selected imaging sequences commonly used in CMR are described together with their clinical applications later in this chapter.

Cardiac and Respiratory Gating

Because most CMR techniques acquire data over multiple heartbeats, cardiac and respiratory motions during image acquisition

TABLE 10.1

Primary Referral Diagnoses in 1,334 CMR Examinations at Children's Hospital Boston

Referral Diagnosis	Number of Studies	Percent
Tetralogy of Fallot	270	20.2
Aorta	198	14.8
Coarctation	116	
Other	82	
Complex 2 Ventricle	187	14.0
TGA	78	
S/p arterial switch	35	
S/p atrial switch	43	
Single ventricle	134	10.0
Septal defects	72	5.4
ASD	39	
VSD	33	
Anomalies of the pulmonary veins	46	3.4
Arrhythmogenic right ventricular cardiomyopathy	41	3.1
Pulmonary atresia with intact ventricular septum	29	2.2
Vascular anomalies (other than aorta)	25	1.9
Kawasaki disease	24	1.8
Congenital coronary anomaly	22	1.6
Cardiac tumor/mass	22	1.6
Vascular ring	21	1.6
Other	243	18.2

ASD, atrial septal defect; TGA, transposition of the great arteries; VSD, ventricular septal defect.

result in image blurring. Several techniques have been developed to overcome this problem. The most common approach to compensate for cardiac motion is to synchronize or “gate” image acquisition with the cardiac cycle. The cardiac cycle is tracked using either the electrocardiogram (ECG) or an optical pulse sensor placed on an extremity (called “peripheral gating”) (Fig. 10.2). Electrocardiographic gating can be accomplished with a high-quality standard ECG trace or with a vectorcardiogram (VCG) signal (4). More recently, a new technique called “self-gating,” which relies on cardiac motion and avoids the use of ECG triggering altogether, has been described (5). Blurring due to respiratory motion can be avoided either by having the patient hold his breath for periods of 5 to 10 seconds during data acquisition or by synchronizing image data acquisition to the respiratory as well as to the cardiac cycle. Another approach that reduces blurring from respiratory motion is to repeat the image acquisition several times and average the data. Respiratory motion can be tracked by either a bellows device placed around the abdomen or by MR navigator pulse that concurrently tracks the position of the diaphragm or cardiac border (Fig. 10.3) (6).

A more desirable approach to avoid motion-induced image blurring is to acquire the MR data fast enough so that cardiac and respiratory motions are adequately resolved. Advances in gradient coil performance, parallel acquisition techniques, and image reconstruction methods have allowed real-time CMR at 20 to 24 frames per second, albeit at the expense of spatial and temporal resolutions (7–10). Real-time imaging may be particularly useful when a patient has an irregular rhythm and to evaluate respiratory-related variations in blood flow and septal position (11). This technology, which is now commercially available on some clinical scanners, may obviate the need for ECG and respiratory triggering.

SEDATION AND MONITORING

Patients undergoing CMR examinations must remain still in the scanner bore for up to 60 minutes to minimize motion artifact during image acquisition and allow planning of successive imaging sequences. Accordingly, the need for performing the examination under sedation or anesthesia and an assessment of the risk–benefit ratio for proceeding under these circumstances should be determined well before the examination date. Multiple factors are taken into account when deciding whether a patient should have an examination with sedation, including the length of the anticipated examination protocol, the child's developmental age and maturity, the child's experience with prior procedures, and the parents' opinion of their child's capability to cooperate with the examination. True claustrophobia in the pediatric age group is rare. In general, most children 7 years of age and older can cooperate sufficiently for a good-quality CMR study. Parents should be provided with a detailed description of the examination and asked to discuss it with their child in an age-appropriate manner in advance to increase the likelihood of a successful study. After proper screening, parents can be allowed into the scanner room to help their child complete the examination. Allowing patients to listen to music or watch movies through a specialized MRI-compatible audiovisual system may reduce anxiety and improve patient cooperation (12).

Strategies for sedation and anesthesia in CMR vary and often depend on institutional preference and resources such as availability of qualified pediatric anesthesiologists. Although it is possible to wait for young children to fall into a natural sleep using a “feed and swaddle” approach, this method may be time-consuming and complicated by early awakening. Sedation can be achieved with a variety of medications (e.g., pentobarbital, propofol, fentanyl, midazolam, chloral hydrate) and is a reasonable approach (13–19). Its principal drawbacks are an unprotected airway and reliance on spontaneous respiratory effort with the associated risks of aspiration, airway obstruction, and hypoventilation. In addition, because images are often acquired over several seconds, respiratory motion will degrade image quality. This motion artifact can be reduced by synchronizing image data acquisition to the respiratory cycle tracked either by a bellows device around the abdomen or by navigator echoes that concurrently image the position of the diaphragm or heart. An alternative strategy to reduce respiratory motion artifacts is to acquire multiple images at the same location and average them, thereby minimizing variations from respiration. The principal limitations of both these strategies are prolonged scan times and incomplete elimination of respiratory motion that can lead to reduced image quality.

Because of these safety and image quality concerns, we and others frequently prefer to perform CMR examinations

Figure 10.1. From signal to image. Top panel: Outside the scanner's magnetic field, the orientation of the spinning (precessing) protons is random. Once inside the scanner, the protons are aligned with the direction of the static magnetic field (B_0). Excitation by a brief pulse of RF energy perturbs the protons into a state of higher energy. Once the RF pulse ceases, the protons return to their original state of energy (relaxation) and emit RF energy. Lower panel: The emitted RF energy is captured by receiver coils (antennas) and undergoes through a series of electronic filters. The raw MR signal is stored as an array of numbers called " k -space." By applying fast Fourier transformation (FFT), the raw MR data stored in k -space is translated into an image.

Figure 10.2. Cine MRI. A: Schematic representation of image data acquisition. Using the ECG signal, the cardiac cycle is divided into multiple, equally spaced acquisition windows. Several lines of k -space are acquired during each acquisition window (a technique called *segmented k -space*). Over several heartbeats, a series of images spanning the cardiac cycle is reconstructed and viewed in cine loop mode (B).

Figure 10.3. Respiratory navigator. The navigator beam is positioned over the right hemidiaphragm and includes lung and liver tissues (top). The motion of the right hemidiaphragm is continuously displayed (bottom) along with the acceptance window (horizontal lines). Only data acquired when the position of the right hemidiaphragm is registered within the acceptance window are used for image reconstruction.

under general anesthesia in children who cannot undergo an awake examination (20,21). This approach, described in detail elsewhere (2,22), is safe, consistently achieves adequate sedation, protects the airway, and offers control of ventilation. Respiratory motion artifact can be completely eliminated by suspending ventilation in conjunction with neuromuscular blockade. Breath-hold periods of 30 to 60 seconds are typically well tolerated, and allow multiple locations to be scanned efficiently.

When utilizing either sedation or anesthesia, it is important that both the nurses and physicians have sufficient experience with these procedures in children with cardiovascular disorders. Continuous monitoring of the ECG, pulse oximetry, end-tidal carbon dioxide, anesthetic gases, blood pressure, and temperature with an MRI-compatible physiologic monitoring system is required (Fig. 10.4). MRI-compatible anesthesia machines are available that can be located in the scanner room and connected to the patient's endotracheal tube by an extended breathing circuit. To maximize patient safety and examination quality, it is recommended that different health care providers be responsible for supervising the imaging and sedation/anesthesia aspects of the study and that both communicate closely with each other.

PATIENT PREPARATION

Prior to bringing the patient into the scanner room, the physician and technologists should review the patient's history, safety screening form, and the most recent chest radiograph to identify implanted devices that may be hazardous in the MRI environment or produce image artifact. A detailed discussion on MRI safety can be found at the end of this chapter and elsewhere (23–25).

Following safety screening, physiologic monitoring devices and hearing protection (for both awake and anesthetized

Figure 10.4. MRI suite equipped with (1) MR-compatible anesthesia machine, (2) physiologic monitoring equipment, and (3) ceiling-mounted in-room scan controls and monitors.

patients) are put in place. A high-quality ECG signal is essential for optimum image quality in cardiac-gated sequences. The signal should be checked both when the patient is outside and then inside the scanner bore. In patients with dextrocardia, ECG leads are best placed on the right chest. Because young children dissipate body heat faster than adults, the scanner room temperature should be adjusted and prewarmed blankets applied to minimize heat loss.

The imaging coil should be chosen to maximize the signal-to-noise ratio over the entire body region to be examined. Because CHD often involves abnormalities of the thoracic vasculature, the coil will usually need to be large enough to cover the entire thorax rather than just the heart. Adult head or knee coils are often appropriate for infants weighing <10 kg, and adult cardiac coil for medium-sized children weighing between 10 and 40 kg. More recently, multichannel coils designed specifically for cardiovascular imaging in infants and young children have become commercially available (Fig. 10.5). Adequate coil coverage and placement should be confirmed early in the examination by reviewing the localizing images.

SAFETY

Standard clinical imaging scanners present no known hazards to biologic materials. Guidelines set by the Food and Drug Administration (FDA) keep the strength of the magnetic fields and the deposition of RF energy well below levels that could cause significant biologic effects. Animal studies evaluating the influence of static magnetic fields have not demonstrated significant biologic effects for fields of up to 2 T (26). Millions of patients have undergone MRI studies without any noticeable immediate or long-term sequelae. The incidence of complications related to CMR examination in patients with CHD is low (1.6%), most of which are minor and transient (1). Not surprisingly, infants with severe cardiorespiratory compromise referred to CMR from the cardiac intensive care unit are more susceptible to adverse events such as transient hypotension and hypoxemia.

Investigations on pregnant human subjects exposed to MR imaging or the MR environment have not demonstrated any adverse outcomes. Current guidelines state that pregnant patients can be accepted to undergo MR scans

Figure 10.5. Multichannel RF coils used in CMR imaging in infants, children, and adults. **A:** 8-channel knee coil used in infants weighing 4 kg or less; **B:** 8-channel pediatric coil used in patients weighing between 4 kg and 10 kg; **C:** 5-channel cardiac coil used in patients weighing between 10 kg and 30 kg; and **D:** 32-channel cardiac coil used in patients weighing 30 kg or more. at any stage of pregnancy if the risk–benefit ratio to the patient warrants that the study be performed (27). Thus, when maternal and fetal health considerations necessitate diagnostic studies, MRI is preferable to methods that use x-rays, such as computed tomography (CT) or standard angiography.

Gadolinium contrast is commonly used in CMR examinations in patients of all ages for angiography and for assessment of myocardial viability, first-pass perfusion, and diffuse fibrosis (28–30). It is important to note that the FDA has not approved the use of contrast agents in CMR; hence its use is off-label. The incidence of adverse events related to gadolinium contrast is very low. In patients with CHD, Dorfman et al. (1) reported an event rate of 0.84%—all were minor and transient events such as nausea, vomiting, or sensation of warmth. Anaphylactic reaction to gadolinium contrast is

exceptionally rare (31). Nephrogenic systemic fibrosis (NSF), previously known as nephrogenic fibrosing dermopathy, is a well recognized but incompletely understood systemic disease characterized by progressive multiple-organ fibrosis. An association between NSF and gadolinium administration was recognized in 2006 (32). Subsequent investigations found that patients with renal failure were at risk for developing this rare but severe complication (33,34). Consequently, most institutions have adopted a policy to avoid using gadolinium contrast in patients with impaired renal function (35). A recent study has shown no new cases of NSF since the institution of a policy of avoiding use of gadolinium contrast in patients with glomerular filtration rate lower than 60 mL/min/m² (36).

Implanted metallic objects are of particular concern in the MR environment since they could potentially undergo undesirable movements if the magnetic field were sufficiently

* Some centers advocate avoiding MRI for an arbitrarily period of time after implantation (usually for several weeks), but such practice is not supported by conclusive published data. A decision to perform MRI examination shortly after cardiac surgery or implantation of a biomedical device must weigh the risk–benefit ratio for the individual patient. (From Shellock FG. Metallic surgical instruments for interventional MRI procedures: evaluation of MR safety. *J Magn Reson Imaging* 2001;13:152–157, with permission from John Wiley and Sons.)

strong and if they contained sufficient ferromagnetic material (Table 10.2). Fortunately, surgical clips and sternotomy wires implanted in the chest and abdomen are typically only weakly ferromagnetic. Furthermore, these devices quickly become immobilized by surrounding fibrous tissue, and MRI can safely be used to study patients with these implants. The wires and clips, however, may cause localized image artifact. Similarly, MRI can be used to image patients with implanted intravascular coils, stents, and occluding devices once the implants are believed to be immobile. Many centers choose to avoid exposing these patients to MRI for an arbitrarily chosen period of time after implantation (usually for several weeks), but such practice is not supported by conclusive published data. A decision to perform MRI examination shortly after cardiac surgery or implantation of a biomedical device must weigh the risk–benefit ratio for the individual patient (37).

Several devices are considered either a relative or absolute contraindication to MRI (37–39). Presence of an intracranial, intraocular, and intracochlear metallic object is considered a contraindication to MRI. The presence of a cardiac pacemaker is also considered a contraindication to MRI (40) although

some reports have suggested that scanning patients who have modern pacemakers may be possible (23,41–44). In 2011, the FDA gave conditional approval to a pacemaker designed specifically to be MRI compatible (45).

Because MRI scanners attract ferromagnetic objects, extreme caution should be used in approaching magnets with objects containing iron or other ferromagnetic materials. Only specially designed MRI-compatible physiologic monitoring equipment should be used in conjunction with MRI studies. There have been several reported cases of patient burns resulting from the use of MRI-incompatible pulse oximeters and ECG monitoring devices.

SUPERVISION AND INTERPRETATION OF MRI EXAMINATION

Detailed pre-examination planning is crucial, given the wide array of imaging sequences available and the often-complex nature of the clinical, anatomic, and functional issues in

patients with CHD. The importance of a careful review of the patient's medical history, including details of all cardiovascular surgical procedures, interventional catheterizations, findings of previous diagnostic tests, and current clinical status, cannot be overemphasized. As with echocardiography and cardiac catheterization, CMR examination of CHD is an interactive diagnostic procedure that requires online review and interpretation of the data by the supervising physician. The unpredictable nature of the anatomy and hemodynamics often require adjustment of the examination protocol, modification of imaging planes, changing sequences, and adjustment of imaging parameters. Reliance on standardized protocols and postexamination review alone in these patients may result in incomplete or even erroneous interpretation.

CLINICAL APPLICATIONS

CMR Examination Techniques

The building blocks of any MRI examination are called “pulse sequences” (Fig. 10.6). An MRI pulse sequence describes the way the magnetic field gradients and RF pulses are applied to produce images with particular characteristics. During the course of a CMR examination, the examiner selects the pulse sequences and prescribes imaging locations and planes to acquire the image data to address specific clinical questions. Some of the pulse sequences used in CMR practice are described below together with their clinical applications.

Figure 10.6. Timing diagram of a SE pulse sequence. The x-axis represents time. The first step is the simultaneous application of a 90-degree RF pulse and a slice-selective gradient (G_{SS}) pulse. The next step is the application of a slice-selective 180-degree RF pulse to refocus the transverse magnetization that lost phase coherence due to inhomogeneities in the magnetic field. To locate the MR signal in space (spatial localization), multiple frequency encoding (G_{PE}) and single-phase encoding (G_{FE}) gradients are applied. The time at which the MR signal (echo) is recorded is called *echo time*, or TE. This sequence results in the acquisition of one line of k -space data. The sequence is repeated N_{2D} times, each with a different phase-encoding value, until all lines of k -space are collected and a 2-D image is reconstructed. The time from onset of one sequence to the next is called *repetition time*, or TR.

Assessment of Cardiovascular Anatomy

Evaluation of cardiovascular anatomy and function in patients with CHD is often inseparable. Several MRI sequences can be used for anatomic delineation; each has particular advantages and provides specific information. In practice, the anatomy in question is often assessed by more than one imaging sequence, yielding overlapping information that increases diagnostic confidence.

Spin Echo MRI

With spin echo (SE) imaging, the MR signal is produced by applying a brief RF pulse that tips the magnetization vector of the hydrogen atoms (spins) 90 degrees relative to the axis of the main magnetic field, followed by a 180-degree refocusing RF pulse (Fig. 10.6). Because of the relatively long time interval between tissue excitation and data sampling, flowing blood will leave the image plane by the time the signal is sampled. The result is an image in which flowing blood appears black, whereas more stationary tissues produce MR signals displayed in varying shades of gray or white (“black blood” imaging) (Fig. 10.7A). Other features of SE pulse sequences include a single image per cardiac cycle (static imaging), high tissue contrast, and, compared with gradient echo pulse sequences, relative insensitivity to inhomogeneities in the magnetic field. In clinical practice, such inhomogeneities are mostly owing to ferromagnetic implants such as sternal wires, prosthetic heart valves, stents, coils, or other implants. SE sequences can also be modified to alter tissue contrast and characterize the composition of structures (e.g., T1 and T2 weighting) (Fig. 10.7B). Standard SE requires several minutes (usually 2 to 4 minutes, depending on heart rate and imaging parameters) to acquire an image dataset. Fast or turbo spin echo (FSE or TSE) requires a much shorter image acquisition time because instead of acquiring a single-phase encoding line for each 90 degrees RF pulse, multiple-phase encoding lines are acquired in rapid succession (called “echo train”). As a result, image acquisition can be completed during 10 to 15 seconds of breath holding. In the TSE sequence, the blood signal is nulled by an inversion pulse (called *double inversion recovery*) rather than relying on blood flow alone.

Standard SE was the workhorse of CMR during the 1980s. In today's clinical practice, standard SE has been largely replaced by FSE or TSE with double inversion recovery (2). Examples of clinical applications include assessment of tissue characteristics (e.g., cardiac tumors), vessel wall imaging (e.g., aortic dissection), evaluation of the pericardium, and anatomic imaging in patients with metallic implants such as stents and prosthetic valves.

Gradient Echo Cine MRI

Gradient echo MR is a class of pulse sequences that produce bright blood images. The fundamental difference between SE and gradient echo sequences is that in the latter the initial RF pulse tips the spins at an angle (called *flip angle*) <90 degrees. Gradient echo sequences are generally faster than SE sequences because the time between spin excitation and signal detection (called “echo time” or TE) is much shorter. The signal from stationary or relatively slow-moving tissues (such as the myocardium) is gray because the spins within the selected slice have reduced signal intensity (i.e., partially saturated) by the rapid repetition of the RF pulse. This is because the spins do not have sufficient time to return to their original unexcited state during the short interval between RF pulses, which result in

Figure 10.7. Short-axis FSE image in a patient with hemangioma of the RVOT. **A:** T1-weighted image showing a slightly hyperintense globular tumor (arrow); **B:** T2-weighted image showing the tumor is markedly hyperintense, consistent with a vascular tumor.

a relatively weak signal. On the other hand, blood that flows into the slice contains unsaturated spins that produce relatively strong signals, hence the term “bright blood” imaging (Fig. 10.8). An important feature of gradient echo sequences is high imaging speed, which allows reconstruction of multiple images during the cardiac cycle that can be displayed in cine loop format. Compared with SE techniques, gradient echo sequences have a relatively low tissue contrast and are more susceptible to inhomogeneities within the magnetic field.

ECG- or VCG-triggered steady-state free precession (SSFP) is the most commonly used cine MRI technique for assessment of cardiovascular anatomy and ventricular function. The brightness of a given tissue in this case is determined primarily by the ratio of T2 to T1 relaxation times, which results in high contrast between the blood pool ($T2/T1 = 360 \text{ ms}/1200 \text{ ms} = 0.3$) and the myocardium ($T2/T1 = 75 \text{ ms}/880 \text{ ms} = 0.085$) and clearly depicts the boundaries of cardiovascular structures (Fig. 10.8) (46). This sequence is known by several proprietary names, including true fast imaging with steady precession, balanced fast field echo (bFFE), and fast imaging employing steady state acquisition (FIESTA). The acquisition time of SSFP cine MRI is short, typically requiring 4 to 10 seconds for each location depending on heart rate, spatial resolution, and other acquisition parameters. The SSFP sequence, however, is highly sensitive to inhomogeneities in the magnetic field such as those induced by implanted metallic devices.

A segmented *k*-space fast (also termed “turbo”) gradient recalled echo (fast GRE) sequence was used extensively during the 1990s, and its accuracy and reproducibility in measuring ventricular dimensions and function have been validated (47,48). Compared with SSFP, the distinction between blood and myocardium on fast GRE images is less sharp, the contrast-to-noise ratio and the temporal resolution are lower, image acquisition time is longer, and images are more susceptible to blood flow effects. On the other hand, fast GRE is less susceptible to inhomogeneities in the magnetic field than SSFP.

In clinical practice, an ECG-gated gradient echo cine MRI sequence is prescribed across the anatomy of interest to yield a stack of contiguous cross-sectional slices that can be displayed on a computer workstation in a multilocation, multiphase (cine loop) format. ECG-gated segmented *k*-space SSFP cine MRI is the sequence of choice for evaluation of cardiac anatomy and function because of its excellent blood–myocardium contrast, high spatial and temporal resolutions, and short acquisition time. Use of a parallel imaging technique (e.g., sensitivity encoding or SENSE) further shortens acquisition

Figure 10.8. ECG-triggered SSFP image in the axial plane in a patient with severe Ebstein anomaly. Note the apical displacement of the tricuspid valve (black arrows), “atrialization” of the right ventricular inflow, markedly dilated right atrium (RA), and the compressed LV.

time (49). The SSFP sequence allows detailed imaging of the cardiac chambers, the atrioventricular and semilunar valves, the papillary muscles and chordae tendineae, the membranous septum, septum primum, and blood vessels (Fig. 10.8). The SSFP sequence, however, is relatively less sensitive to flow disturbances due to stenotic or regurgitant jets compared to fast GRE. Alternatively, a velocity-encoded cine (VEC) MRI sequence can be prescribed when further delineation of abnormal flow jets is desirable.

Three-Dimensional Steady State Free Precession MRI

This cardiac-triggered SSFP technique acquires a 3-D image volume over a period of 4 to 7 minutes of free breathing (50,51). The motion of the diaphragm is tracked with a navigator pulse and image data is accepted only when the position of the diaphragm lies within a narrow window defined by the operator (Fig. 10.3), thus avoiding artifacts from respiratory motion. The volume elements (voxels) of the image dataset are typically isotropic, which allows off-line reformatting of the image volume in any arbitrary plane. This imaging technique does not require administration of contrast agents and provides high-resolution static imaging of both intracardiac and extracardiac anatomy (Fig. 10.9).

Coronary Artery Imaging

The origin and course of the epicardial coronary arteries can be evaluated by several MRI techniques. Most of the published experience with MRI evaluation of the coronary arteries is based on a cardiac-triggered, navigator-gated, free-breathing 3-D magnetic resonance angiography (MRA) sequence (52). This technique has been used successfully in patients with various congenital anomalies of the coronary arteries (Fig. 10.10) and in Kawasaki disease (53–57).

Contrast-Enhanced Three-Dimensional MRA

Gadolinium (Gd)-enhanced 3-D MRA is ideally suited for imaging of extracardiac vascular anatomy. Examples of common clinical applications include imaging of the aorta and its branches, pulmonary arteries, pulmonary veins, systemic veins, aortopulmonary and venous–venous collateral vessels, systemic-to-pulmonary artery shunts, conduits, and vascular grafts (14,58). Although this technique is mostly used for imaging of extracardiac anatomy, we have also found it useful in the evaluation of intra-atrial systemic and pulmonary baffles (e.g., Mustard or Senning operations and Fontan palliation), as well as for imaging of the outflow tracts (e.g., repaired TOF and the arterial switch operation [ASO]). In addition, Gd-enhanced 3-D MRA clearly delineates the spatial relationships between vascular structures, the tracheo-bronchial tree, chest wall, spine, and other landmarks that may be useful for planning interventional catheterization or surgical procedures (Fig. 10.11). More recently, imaging acceleration techniques have been applied to shorten the acquisition time to 2 to 5 seconds, thereby permitting multiple 3-D volume sets to be acquired as the contrast passes through the circulation, producing a “time-resolved” 3-D MRA (59). However, given the trade-offs between spatial and temporal resolutions, the clinical utility of this imaging technique awaits further study.

In practice, the contrast (e.g., gadopentetate dimeglumine 0.2 mmol/kg) is infused through a peripheral intravenous cannula either by hand or by a power injector. The patient is

instructed to hold his/her breath and imaging acquisition is initiated. The time delay between start of contrast injection and data acquisition is determined either by a magnetic resonance (MR) fluoroscopic method that allows real time visualization of the arrival of the contrast bolus to the heart or by a bolus tracking technique. Two or more sequential 3-D MRA data acquisitions are usually obtained 10 to 15 seconds apart during suspended respiration.

Ventricular Function

Technique. ECG- or VCG-triggered SSFP is the preferred cine MRI technique for assessment of ventricular function. In patients in whom image artifacts from metallic implants obscure the ventricles, a fast (turbo) GRE sequence can be used because it is less susceptible to inhomogeneities in the magnetic field (60). ECG-triggered SSFP cine MRI is acquired during short periods of breath holding. Depending on heart rate and image acquisition parameters (matrix size, number of k -space lines per segment, and the scanner's gradient system capabilities), high-resolution acquisition may last 7 to 10 seconds per slice. A modest decrease in spatial and temporal resolutions will lower the acquisition time to 4 to 5 seconds while producing diagnostically acceptable images. The use of SENSE technology allows shorter acquisitions time by a factor of 2 to 4 seconds (at the expense of reduced signal-to-noise ratio), an increase in spatial or temporal resolutions while maintaining the same acquisition time, or a combination of the two. Patients are instructed to hold their breath at end expiration to minimize variations in the position of the diaphragm and, consequently, the heart. In patients who are incapable of holding their breath, images are acquired during free breathing either with multiple signal averages, with respiratory triggering, or with real-time MR fluoroscopy (61,62).

Quantitative evaluation of ventricular function is achieved by obtaining a series of contiguous SSFP cine MRI slices that cover the ventricles in short-axis (Fig. 10.12). This involves the following steps:

- Two-chamber plane (also known as vertical long-axis plane):* A slice is prescribed parallel to the plane of the interventricular septum based on previously obtained scout images in the axial (transverse) plane (Fig. 10.12A). In patients with a biventricular heart and a systemic left ventricle (LV), the slice extends from the center of the mitral valve to the LV apex. In patients with a systemic right ventricle (RV) (e.g., atrial switch operation for transposition of the great arteries [TGA]), it is advantageous to place the slice between the center of the tricuspid valve and the RV apex. In patients with a single ventricle, the slice is placed between the center of the atrioventricular (AV) valve(s) and the ventricular apex. This acquisition accounts for the orientation of the ventricles in the transverse plane of the chest.
- Four-chamber plane (also known as horizontal long-axis plane):* A stack of slices (usually four) is prescribed from an end-diastolic image of a slice acquired perpendicular to the previous two-chamber cine sequence (Fig. 10.12B). This acquisition accounts for the superior–inferior orientation of the ventricles in the chest.
- Short-axis plane:* Multiple equidistant slices are prescribed from an end-diastolic image of the previous four-chamber cine sequence covering the ventricles from the plane of the AV valve(s) to the cardiac apex (Fig. 10.12C). The first slice is placed at the level of the AV annuli by connecting the right coronary artery (seen in cross section in the right AV groove) with the left circumflex coronary artery (seen in the left AV groove). Subsequent slices

Figure 10.9. Free-breathing (navigator-gated), ECG-triggered, isotropic, 3-D SSFP imaging in a patient with Mustard palliation of TGA. are positioned in equidistance through the cardiac apex (Fig. 10.12D). In most patients, 12 slices will cover the ventricles from base to apex with adjustment of slice thickness between 4 and 8 mm and the interslice spacing from 0 to 2 mm. Using these guidelines, the range

of ventricular lengths covered is 4.8 to 12 cm. In some infants, the number of slices can be reduced, whereas in older patients with markedly dilated ventricles, or in those with abnormally shaped ventricles (e.g., basal RV “shoulder” protruding past the plane of the tricuspid valve), the number of slices may need to be increased. We prefer not to increase the slice thickness >8 mm and interslice spacing >2 mm to avoid partial volume effect and to minimize extrapolation of interslice data.

Image Analysis. Accurate determination of ventricular volume requires clear depiction of the blood–myocardium boundary. Adjustment of the image brightness and contrast on the computer screen can facilitate visualization of that boundary. By tracing the blood–endocardium boundary, the slice’s blood pool volume is calculated as the product of its cross-sectional area and thickness (which is prescribed by the operator). The left ventricular papillary muscles and the major trabeculations of the RV (e.g., septal and moderator bands) are excluded from the blood pool and are considered part of the myocardium (63,64). Ventricular volume is then determined by summation of the volumes of all slices. The process can be repeated for each frame in the cardiac cycle to obtain a continuous time–volume loop or it may be performed only on end-diastolic (maximal area) and end-systolic (minimal area) frames to calculate diastolic and systolic volumes. From these data one can calculate left and right ventricular ejection fractions and stroke volumes. Since the patient’s heart rate at the time of image acquisition is known, one can calculate left and right ventricular outputs as the product of stroke volume and heart rate. Ventricular mass is calculated by tracing the epicardial borders and calculating the epicardial volume, subtracting the endocardial volume, and multiplying the resultant muscle volume by the specific gravity of the myocardium (1.05 g/mL).

Several approaches to measurements of biventricular size and function have been reported. In general, these can be divided into two broad categories: (a) methods that rely on summation of discs (Simpson principle) (65); and (b) methods that rely on modeling the chamber or extrapolation of sparse data (66–68). In the first category, each of the slices covering the ventricles is contoured at least once at end diastole (largest volume) and at end systole (smallest volume). Some groups have advocated the use of images obtained in axial or oblique long-axis planes (69,70). The major advantage of this approach, as compared with analysis based on short-axis images, is the ease of determining the planes of the AV and semilunar valves. This advantage is likely responsible for the slightly higher reproducibility of measurements using older software (70). However, this approach limits evaluation of ventricular mass because the epicardial and endocardial borders of the diaphragmatic wall of the heart are not clearly defined. Recent development of techniques that incorporate cross-references between long-axis and short-axis images has greatly reduced the difficulty in determining valve plane on short-axis images (Fig. 10.12) (71). Moreover,

most reports on normal values as well as the majority of the literature on ventricular size and function in CHD and acquired heart disease are based on analysis of short-axis images (63,72,73).

In the second category, either a formula based on a geometrical model or extrapolation from sparse data is used to generate ventricular volumes (66–68). The major advantage of this approach is shorter analysis time but it is disadvantaged by reduced accuracy.

In our center, ventricular volumes and mass are measured from short-axis cine SSFP images (64). Cross-referencing the short-axis images with left and right ventricular two-chamber (vertical long-axis) and four-chamber (horizontal long-axis) cine SSFP facilitates accurate determination of the AV and semilunar valves planes during systole and diastole (71). To optimize interstudy reproducibility in patients followed longitudinally, contours should be compared side-by-side with those from previous studies. Saving the contour files along with previous studies facilitates this comparison. On average, total analysis time is approximately 25 minutes and decreases with operator experience (71).

Manufacturers of MRI scanners and several third-party companies offer software packages that automatically perform the above calculations. Development of algorithms for automatic border detection has facilitated the application of these techniques, but further refinements are required to improve its accuracy (74–77).

Potential Sources of Errors in Determining Ventricular Volumes by MRI. Translational motion of the ventricles in the base-to-apex direction is most prominent at the base of the heart. Given that the prescribed short-axis slices are fixed in space, there is significant through-plane motion in the basal slices during the cardiac cycle. As a result, the first (and sometimes also the second) most basal slices may contain atrial blood pool during part of the cardiac cycle because the AV junction has moved out of the imaging plane during systole. To avoid erroneous inclusion of the atrial blood pool in the calculation of ventricular volume, the image dataset is examined to distinguish between ventricular and atrial structures. In general, when a slice contains a ventricular chamber throughout the cardiac cycle, the chamber's cross-sectional area decreases in systole and its wall thickness increases. In contrast, in a slice containing ventricular myocardium in diastole and atrial blood pool in systole, the chamber's cross-sectional area increases and wall thickness decreases. Recent development of techniques that incorporate cross-references between long-axis and short-axis images has greatly reduced the difficulty in determining valve plane on short-axis images (71).

Another potential source of error in measurements of ventricular volumes is when the left ventricular papillary muscles and the right ventricular trabeculations are traced in an inconsistent fashion during systole and diastole. For example, exclusion of the papillary muscles from the blood pool in diastole, but not in systole, will lead to underestimation of end-systolic volume, stroke volume, and ejection fraction.

Inconsistent position of the diaphragm during breath holding can lead to spatial variations in the location of the ventricles during acquisition of the short-axis images. This source of error in volume calculation can be minimized by instructing the patient to hold breath at end expiration (78,79).

Accuracy, Reproducibility, and Reference Values of Ventricular Volumes and Function by CMR. The combination of a 3-D dataset, clear distinction between the blood pool and the myocardium, and high spatial and temporal resolutions allow for accurate measurements of any cardiac chamber regardless of its morphology and without geometric assumptions. Much research was performed in the late 1980s and early 1990s on in vitro phantoms, animal models, and in human subjects to validate the accuracy of CMR measurements of ventricular volumes and mass (80–86). More recently, attention has focused on investigating the test characteristics of CMR assessment of chamber dimensions and function, and on comparison of its accuracy and reproducibility with those of echocardiography and radionuclide techniques (87–90). Germain et al. (91) in a study of 20 patients with “good echocardiographic windows,” found that the mean (\pm SD) interstudy variability of CMR measurement of left ventricular mass was $6.75 \pm 3.8\%$ compared with $11 \pm 6.4\%$ for M-mode echocardiography. Bellenger et al. (92) calculated that the sample size required to detect changes in left ventricular volumes, ejection fraction, and mass by CMR in patients with heart failure were substantially smaller compared with published values for 2-D echocardiography. For example, to detect a 10-mL change in end-diastolic volume (with 90% power and $p < 0.05$), 12 subjects must be studied by CMR versus 121 patients examined by 2-D echocardiography; a 3% change in ejection fraction requires 15 CMR versus 102

echocardiograms; and a 10-g change in mass requires 9 CMR versus 273 echocardiograms. Ioannidis et al. (93) compared the accuracy of single-photon emission computed tomography (SPECT) for assessment of left ventricular volumes and ejection fraction with that of CMR. Although the two modalities correlated well, compared with CMR, there was a substantial variation in individual measurements by SPECT. Half of the SPECT ejection fraction determinations deviated by at least 5% from CMR-obtained values and one in four deviated by at least 10%. In patients with CHD, Mooij et al. (71) demonstrated low interobserver coefficient of variations in 60 children, most with abnormalities affecting the right heart. The coefficient of variations for RV volumes and mass ranged from 6.4% to 11.3% and for LV volumes and mass from 3.6% to 10.5%.

Because CMR techniques continue to evolve, different imaging sequences may yield different measurements of ventricular dimensions and function. Several studies have compared the normal range of left and right ventricular mass, volume, and ejection fraction measured by cine SSFP with values obtained by the fast (turbo) GRE cine technique (94). In general, compared with fast GRE, measurements based on cine SSFP resulted in larger ventricular volumes, lower mass, and similar ejection fraction. Importantly, both intraobserver and interobserver variations were lower with SSFP measurements. The range of SSFP-based left and right ventricular volumes, mass, and ejection fraction in 60 healthy subjects ranging in age from 20 to 65 years was published by Alfakih et al. (63). Other groups have published similar data in healthy adults (72,95). Several reports on SSFP-based normal values of ventricular dimensions in children have been published (73,96,97), but data in infants and young children are still lacking.

Assessment of Myocardial Function

Although ejection fraction and other ejection phase indices such as shortening fraction and velocity of circumferential fiber shortening are useful markers of ventricular function and provide valuable prognostic information, they are influenced by preload, afterload, heart rate, and the contractile state of the myocardium. Moreover, load-dependent ejection phase indices such as ejection fraction can be normal despite depressed contractility and, conversely, can be depressed despite having normal contractility. Therefore, assessment of ventricular function by load-independent indexes provides useful information on the contractile state of the myocardium. A detailed discussion of ventricular mechanics is beyond the scope of this chapter and can be found elsewhere (98,99).

Assessment of the contractile state of the myocardium by CMR has been investigated by Setser et al. (100) using normalized maximal ventricular power. An alternative approach is to adjust ejection phase variables such as ejection fraction, velocity of fiber shortening, or wall strain to end-systolic stress. With knowledge of left ventricular end-systolic volume, mass, and pressure (estimated based on mean arterial blood pressure measured by sphygmomanometry), end-systolic stress can be estimated as follows (99):

$$P = (2/3)\sigma_p(\ln V_0 - \ln V_c)$$

where

V_c is cavity volume

V_0 is chamber volume (cavity volume + myocardial volume)

σ_p is average of orthogonal fiber stresses $(\sigma_{p\phi} + \sigma_{p\theta})/2$.

It should be noted that experience with this method in CMR is lacking.

Analysis of Regional Wall Motion

A simple qualitative approach is to visually evaluate segmental ventricular wall motion and thickening imaged from long- and short-axis cine SSFP sequences. The LV is divided into 17 segments, as recommended by the American Heart Association (Fig. 10.13) (101) and the RV is divided into nine segments as described by Klein et al. (102) (Fig. 10.14). Ventricular wall motion is classified as normal (appropriate systolic wall motion normal to the local wall segment accompanied by myocardial thickening indicative of fiber shortening), hypokinesis (reduced systolic motion and wall

thickening), akinesis (no appreciable systolic wall motion and no change in wall thickness), or dyskinesis (outward systolic wall motion without myocardial thickening). A more objective approach is to define the endocardial and epicardial boundaries of the ventricles throughout the cardiac cycle, and, using commercially available software, quantitatively analyze wall motion and myocardial thickening (103). The main drawback of this approach is that it is time-consuming, which hinders its acceptance into routine clinical practice. However, improvements in automatic border detection can shorten the process and may lead to increased use of this technique.

Analysis of Myocardial Strain and Stress

Analysis of myocardial strain provides information on regional myocardial function. Although myocardial strain can be calculated from velocity information obtained by phase-velocity cine MRI technique (similar to tissue Doppler imaging), most investigators favor a technique called *myocardial tagging* using spatial modulation of magnetization (SPAMM) (104). This technique is a modification of cine gradient echo MRI that allows tracking of myocardial motion in two or three spatial dimensions over time. Using a preparatory RF pulse, saturation bands or “tags” that appear as dark lines or stripes are applied across the image at end diastole (Fig. 10.15). On subsequent images, the stripes (tags) will remain unchanged on stationary tissue such as the chest wall and spine but will change their position on moving tissues such as ventricular myocardium. As the myocardium moves during the cardiac cycle, the tags follow it and their rotation, translation, and deformation can be tracked allowing for calculation of myocardial strain and strain rate (105). This analysis can be done during systole or diastole and in two or three dimensions (106). Early studies with myocardial tagging were mostly done by manual tracking of the tags, a time-consuming process that hindered the clinical use of this technique. A modified technique for the analysis of myocardial tagging data, harmonic phase imaging (HARP), greatly shortens analysis time because it does not require manual tracing of the tags (107). This technique relies on automatic analysis of the raw MRI data for changes in phase between images. With recent advances in automatic analysis of the tag data and fast image acquisition and display techniques, it is now possible to evaluate myocardial strain in real time (10).

Myocardial tagging has been shown to be an important research tool in the study of normal left (108–110) and right (102,111) ventricular mechanics in healthy volunteers. In the clinical arena, analysis of wall strain by myocardial tagging has provided useful information in patients with ischemic and valvular heart disease (112–115). In a study of 211 patients with chest pain, Kuijpers et al. (116) demonstrated that myocardial tagging detects more segments with regional wall motion abnormalities by dobutamine stress CMR (DSMR) than visual assessment alone. Evaluating patients with CHD, Fogel et al. (117–119) used myocardial tagging to characterize patterns of wall motion and strain in patients with functionally

single ventricles. As new fast MRI techniques coupled with automatic analysis of myocardial tagging become more widely available, the clinical application of ventricular strain analysis will likely expand. Further research is required to determine the clinical implications of the strain data and how it can be used to assess prognosis and guide patient management.

Tissue tracking, which is a relatively new method to assess myocardial motion and deformation by echocardiography (120), has recently been successfully applied to CMR (Fig. 10.16) (121). By comparing differences in signal intensities (speckles) from one frame to the next, specialized software tracks the motion of the myocardium and calculates displacement, strain, and strain rate in user-defined regions of the ventricles. Advantages of this technique include the ability to perform the analysis on existing cine CMR images and no requirement for additional sequences such as myocardial tagging. Using this technique, Ortega et al. (122) recently demonstrated in patients with repaired TOF that indexes of left ventricular dyssynchrony were associated with death and sustained ventricular tachycardia.

Stress CMR

There is a growing body of literature on the use of DSMR in the evaluation of myocardial ischemia in adults with coronary artery disease (see discussion in the section on myocardial ischemia below). Several studies have evaluated the use of stress CMR in patients with CHD. In a study of 32 children with congenital and acquired pediatric heart disease, Strigl et al. (123) demonstrated the feasibility of dobutamine CMR for evaluation of stress-induced wall motion abnormalities. Using a protocol that included dobutamine doses up to 40 $\mu\text{g/kg/min}$ and atropine to attain a target heart rate ($0.85 \times [220 - \text{age}]$), the authors demonstrated excellent interobserver agreement (100%) for test positivity and good agreement (92%) for segmental wall motion score. Tulevski et al. (124,125) used a low-dose (15 $\mu\text{g/kg/min}$) dobutamine to evaluate the functional reserve of the LV and RV in asymptomatic and minimally symptomatic patients with repaired TGA, physiologically corrected TGA, and pulmonary outflow obstruction. Compared with controls, patients with systemic RV had decreased functional reserve. In another study from the same group, Dodge-Khatami et al. (126) showed that the functional reserve of the systemic ventricle is comparable in healthy adults and in patients with unoperated, physiologically

Figure 10.15. Myocardial tagging in a patient with hypertrophic cardiomyopathy. **A:** ECG-triggered, breath-hold SSFP image showing asymmetric septal hypertrophy. **B:** Diastolic frame showing the undistorted tags before the onset of systole; **C:** Systolic frame showing distortion of the myocardial tags over the left ventricular free wall with little distortion of the tags over the septum, indicating reduced septal myocardial strain.

corrected TGA. Roest et al. (127) demonstrated the feasibility of assessing biventricular dimensions and function by CMR during supine exercise, a method that provides an alternative to pharmacologic stress.

Diastolic Function

Diastole is a complex process during which the force of the myofibers is restored (128). A detailed discussion of diastolic ventricular mechanics is beyond the scope of this chapter and can be found elsewhere in this text. Researchers have utilized

various modalities and a wide array of parameters to assess diastolic function, such as changes in pressure and chamber dimensions, wall thinning, myocardial velocities and strain, and a wide range of flow-derived variables obtained by Doppler interrogation of the AV valves and pulmonary veins. With the exception of direct pressure measurements, MRI can also evaluate all of the above variables (129–134). For example, Helbing et al. (129) used CMR to measure blood flow through the tricuspid and pulmonary valves as well as changes in right ventricular dimensions to assess diastolic function after TOF repair. Although the data derived from analysis of blood flow

Figure 10.16. Tissue tracking CMR. The software tracks the motion of the left ventricular myocardium throughout the cardiac cycle on short-axis cine SSFP images (top panel), analogous to speckle tracking echocardiography. The tissue velocity, strain, and strain rate versus time are calculated (lower three panels).

and chamber dimensions by MRI are not fundamentally different from similar data obtained by other techniques, MRI offers an advantage in terms of its ability to track tissue motion and deformation during the cardiac cycle using tissue tagging techniques (131,133,135). Fogel et al. (131) used myocardial tagging to study left ventricular diastolic strain in 11 infants with structurally normal heart. They demonstrated inhomogeneities in both circumferential lengthening (E_2) and radial thinning (E_1). Another investigation has demonstrated in a canine model that measurements of the velocity of myocardial untwisting and recoil rate assessed by MRI using tissue tagging correlate closely with the time constant of relaxation or tau (τ) ($r = -0.86$), was unaffected by left atrial pressure, and that τ but not loading conditions was an independent predictor of the recoil rate (133). Thus, the rate of recoil of torsion derived by tissue tagging may provide a noninvasive preload independent isovolumic phase measure of ventricular relaxation.

Flow Analysis

Quantitative and qualitative assessment of blood flow is frequently used in functional MR evaluation of congenital and acquired pediatric heart disease (136). Qualitative evaluation of abnormal flow patterns is used to visualize turbulent flow jets related to stenotic or regurgitant valves or abnormal communications between cardiac chambers or blood vessels (e.g., septal defects, patent ductus arteriosus (PDA), systemic-to-pulmonary shunts, etc.). Site-specific quantification of flow rate, flow velocity, stroke volume, and minute flow can, in principal, be measured across any blood vessel within the central cardiovascular system.

Technique. An ECG-gated VEC MRI sequence, a type of gradient echo sequence, can be used to measure blood flow velocity and quantify blood flow rate (136,137). The VEC MRI technique is based on the principle that the signal from hydrogen nuclei (such as those in blood) flowing through specially designed magnetic field gradients accumulates a predictable phase shift that is proportional to its velocity. Multiple phase images are constructed across the cardiac cycle in which the signal amplitude (intensity) of each voxel is proportional to mean flow velocity within that voxel. Using specialized software, regions of interest around a vessel are defined, and the flow rate is automatically calculated as the product of the mean velocity and the cross-sectional area (Fig. 10.17).

In practice, an imaging plane is prescribed perpendicular to the vessel of interest and two sets of multiphase images are reconstructed following a VEC MRI acquisition: a set of *magnitude images* that provide anatomic information and a set of *phase images* in which the velocity information is encoded. For each acquisition, the operator prescribes the field of view, matrix size, and slice thickness, which, in turn, determine spatial resolution. Greil et al. (138), in an in vitro study using a pulsatile flow model, found that spatial resolution is important for accurate measurements of flow rate by VEC MRI with an optimal number of pixels within the cross section of the vessel of interest ≥ 16 . Other variables such as the angle between the prescribed imaging plane and flow direction, velocity encoding range, flip angle, and slice thickness must also be considered. Other known caveats of quantitative assessment of blood flow by VEC MRI include flow aliasing and dephasing secondary to turbulent flow. Aliasing can be avoided by prescribing a velocity encoding range higher than the maximal velocity within the target vessel. Avoiding dephasing secondary to turbulent

Figure 10.17. Flow velocity cine MRI. **A:** Schematic representation of phase velocity encoding. **Left panel:** A magnetic field gradient (G_x) is briefly applied in the velocity encoding direction (x) causing phase variations to develop. **Right panel:** The gradient is then reversed so that it has equal magnitude and duration but opposite polarity. In stationary tissue, there is no net phase shift because the reversal of the gradient field cancels the effect of the initial gradient application. In contrast, flowing blood in the vessel is now in a different location and is therefore exposed to a different gradient strength (shaded region). Consequently, a net phase shift will result that is proportional to flow velocity. **B:** A typical phase-velocity cine MRI pulse sequence diagram (rf, radiofrequency; G_z , slice select gradient; G_y , frequency select gradient; G_x , phase encoding gradient; DAQ, data acquisition window). **C:** Transverse (axial) view of phase-velocity cine MRI perpendicular to the ascending aorta. **Top panel:** Phase-sensitive image. The signal intensity in this image is linearly proportional to flow velocity. Flow direction is encoded in black (inferior-to-superior) or white (superior-to-inferior). **Bottom panel:** Magnitude image reconstructed based on the amplitude of the tissue signal intensity. To measure the flow in the ascending aorta, a region of interest (*circle*) is placed using off-line computer software. **D:** Flow-time curve. Instantaneous flow rates are calculated multiple times during the cardiac cycle by integrating the flow velocities across the vessel cross-sectional area. The area under the curve represents the stroke volume. Minute flow is calculated by multiplying the stroke volume by the heart rate.

blood flow can be achieved by shortening the echo time, prescribing a thinner slice thickness, or repositioning the imaging slice proximal or distal to the turbulent jet.

Accuracy of Blood Flow Measurements by MRI. VEC MRI flow calculations have been shown by in vitro and in vivo studies to be accurate and reproducible (138–143). In vitro studies have demonstrated that measurements of continuous flow are accurate within 5% of reference standard (144,145). Greil et al. (138) demonstrated that the accuracy and reproducibility of in vitro pulsatile flow measurements by VEC MRI is $0.8 \pm 1.5\%$. Evans et al. (143) found a strong correlation ($r^2 = 0.99$) with a 95% confidence interval of ± 0.07 L/min over a range of flow rates 0.125 to 1.9 L/min. Powell et al. (140), in a phantom model that mimics flow condition in the aorta of a child (flow rates 1.25 to 3.5 L/min), found a similarly strong correlation, a close agreement (bias = -0.045 L/min), and 95% limits of agreement of -0.19 to 0.1 L/min.

The accuracy of in vivo VEC MRI measurements of blood flow has been demonstrated by numerous studies. Investigators have used ventricular stroke volume, thermodilution, Fick principle, indicator dilution, and flow probe measurements as reference standards, showing strong correlations with VEC MRI (140,146–152). Hundley et al. (151) found that ascending aorta flow in 23 adults was within 4% of flow measurements by the Fick method and within 5% measured by thermodilution. Evans et al. (143), in a study of 10 adult subjects, demonstrated an average difference between pulmonary (Q_p) and systemic (Q_s) flow ratio of 5%. Powell et al. (140), in a study of 20 healthy volunteers, found that Q_p/Q_s closely approximated unity (mean \pm SD = 0.99 ± 0.1 , range 0.85 to 1.19). Beerbaum et al. (139), in a study of 50 children

with atrial or ventricular septal defects (VSDs) who underwent concomitant cardiac catheterization, reported a mean difference between VEC MRI and oximetry of 2% (2SD = -20% to $+26\%$). Powell et al. (153), in a study of 20 patients with atrial septal defect (ASD), found a mean difference between VEC MRI and oximetry of 2.3% with a reproducibility of repeat VEC MRI flow measurements of $1.1 \pm 4.2\%$ in the main pulmonary artery and $0.7 \pm 5.4\%$ in the ascending aorta (Fig. 10.18).

Clinical Applications. Measurements of blood flow are an integral element of functional assessment by MRI in a wide range of clinical scenarios. Examples include measurement of cardiac output (151,154), pulmonary-to-systemic flow ratio in patients with intra- and extracardiac shunts (139–141,153,155,156), regional flow to selected organs or vascular beds (e.g., patients with vascular malformations) (157–159), valvular regurgitation in patients with native and postoperative lesions (e.g., pulmonary regurgitation after TOF repair) (160–170), differential lung perfusion (e.g., branch pulmonary artery stenosis) (171–173), quantification of aortopulmonary collateral flow (174,175), AV valve inflow (129), estimation of pressure gradient (170,176,177), and a variety of other clinical scenarios.

Keeping in mind the known limitations of VEC MRI (136,138,178), site-specific quantification of flow rate, flow velocity, stroke volume, and minute flow can provide useful hemodynamic information in a wide range of clinical scenarios. Pharmacologic stress can be used to provide additional information on functional reserve (179). For example, using either dipyridamole or adenosine for vasodilation of the coronary vascular bed, coronary flow reserve can be assessed (180). An inherent strength of functional assessment by MRI

Figure 10.18. Accuracy of phase velocity cine (PVC) MRI measurements of blood flow in 20 patients with interatrial shunt (From Hundley WG, Meshack BM, Willett DL, et al. Comparison of quantitation of left ventricular volume, ejection fraction, and cardiac output in patients with atrial fibrillation by cine magnetic resonance imaging versus invasive measurements. *Am J Cardiol* 1996;78:1119–1123, with permission). A: Mean pulmonary-to-systemic (Q_p/Q_s) flow ratio by oximetry versus mean Q_p/Q_s by PVC MRI. B: The difference in Q_p/Q_s versus mean Q_p/Q_s by PVC MRI and oximetry. The mean difference was 0.06 L/min (solid line) and ± 2 standard deviations from the mean (95% limits of agreement) were -0.42 and 0.54 L/min (dashed lines). (Reprinted from Powell et al. Comparison between phase-velocity cine magnetic resonance imaging and invasive oximetry for quantification of atrial shunts. *Am J Cardiol* 2003;91:1523–1525, with permission from Elsevier.)

is the ability to measure the same variable by different methods, thus allowing for internal validation of the functional data. For example, in a patient with an ASD, the pulmonary-to-systemic flow ratio can be assessed based on (a) flow measurements in the main pulmonary artery and ascending aorta; (b) flow measurements through the tricuspid and mitral valves (typically obtained in a single acquisition perpendicular to plane of the AV valves); and (c) LV and RV stroke volumes obtained by short-axis cine MR. Although standard VEC MRI techniques require 2 to 4 minutes of data acquisition in each site, developments of faster imaging strategies (e.g., segmented k space acquisition and parallel processing) have greatly shortened the acquisition time (156,181–184). Although these techniques allow for data acquisition during a short period of breath holding (10 to 14 seconds), the physiologic effects of suspended respiration may alter intrathoracic pressure and affect flow measurements. Sakuma et al. (185) demonstrated that flow measurements during large lung volume breath holding significantly underestimated cardiac output (4.47 ± 0.63 vs. 6.09 ± 0.49 L/min), whereas cardiac output measurements during small lung volume breath-holding was similar to that obtained during free breathing. Development of real-time velocity-encoded techniques has a potential utility analogous to color Doppler in echocardiography (169). This technique has recently proved valuable in providing unique physiologic information in patients with Fontan circulation (186).

The preceding discussion focused on through-plane flow measurements. When velocity information is measured in the three orthogonal planes (anterior–posterior, superior–inferior, and through plane), multidimensional flow imaging and shear stress calculation can be accomplished (187–190). 3-D flow vector mapping is a useful adjunct to cine flow imaging because it provides dynamic 3-D flow maps that can readily detect abnormal flow patterns (Fig. 10.19).

Myocardial Perfusion and Viability

Compared with the adult population, myocardial ischemia related to coronary artery disease is uncommon in infants and children. In the pediatric population, ischemia may be associated with congenital coronary abnormalities such as

anomalous origin of a coronary artery from the pulmonary artery or from the opposite sinus of Valsalva, or acquired conditions, most notably Kawasaki disease. Alternatively, the coronary circulation may be compromised in postoperative patients, especially those whose procedure involved relocation of the coronary arteries (e.g., ASO). Patients who have undergone heart transplantation are also at risk for the development of accelerated coronary artery disease and abnormalities of the coronary microvasculature.

In comparison with nuclear techniques, cardiac MRI is a relatively young tool for detection of myocardial ischemia and viability. As a result, one should remember during the subsequent discussion that the available data on its clinical utility and applicability are considerably smaller than for the more established techniques. This limitation is perhaps offset by the fact that data specific to children and young adults are scarce for all of the non-invasive techniques. The feasibility of assessing myocardial perfusion and viability by CMR in children and patients with CHD has been demonstrated with encouraging results (191–195).

Myocardial Ischemia. Currently, the two most widely used CMR techniques to detect ischemia are DSMR and first-pass myocardial perfusion (196–198). DSMR is performed using a protocol similar to dobutamine stress echocardiography (DSE) with increasing doses of dobutamine up to 40 to 50 $\mu\text{g/kg/min}$ and the addition of atropine if necessary to reach the target heart rate. The goal of the test is to detect ventricular myocardium supplied by a stenotic coronary artery. At rest, the myocardial blood supply/demand ratio may be sufficient to allow normal wall motion and thickening. However, with increasing metabolic demand under pharmacologic stress, ischemia may be induced and wall motion is impaired. Imaging is usually performed with breath-hold cine SSFP MRI, thereby providing high-quality images of left ventricular wall motion and thickening. Nagel et al. (199) compared the sensitivity and specificity of DSMR with that of DSE in 208 patients for the detection of >50% coronary artery stenosis determined by coronary angiography. Compared with DSE, DSMR was more sensitive (86.2% vs. 74.3%), had a higher specificity (85.7% vs. 69.8%), and better accuracy (86% vs. 72.7%) ($p < 0.05$ for all). CMR has a particular advantage over echocardiography in patients who have poor acoustic windows (up to 15% of studies in adults).

First-pass myocardial perfusion CMR can also be used to diagnose myocardial ischemia. After intravenous injection of a

Figure 10.19. 3-D flow vector mapping in the aortic root and proximal ascending aorta in a patient with Marfan syndrome. The origin of the flow is depicted as a *blue dot* and the *red line* represents the direction and velocity of the flow.

Figure 10.20. First-pass myocardial perfusion in a patient with anterior septal myocardial infarction. **A:** Four short-axis slices (top frame, basal slice; bottom frame, apical slice) before arrival of the contrast; **B:** The contrast enters the RV; **C:** The contrast enters the LV but not the coronary arteries (note the bright signal from the blood pool but not from the myocardium); **D:** Segments with well-perfused myocardium show bright signal whereas the hypoperfused anterior septal segment remains dark (arrows).

gadolinium-based contrast agent, the enhancement pattern of the myocardium is evaluated during the first transit of the bolus through the heart. The appearance of contrast will be attenuated, both in amplitude and rate, in regions of compromised coronary blood flow (Fig. 10.20). In practice, the contrast (e.g., gadopentetate dimeglumine 0.05 to 0.1 mmol/kg) is infused through a large bore cannula using a power injector at a rate of 3 to 5 mL/s. With the patient holding his or her breath, the heart is rapidly imaged in multiple planes for approximately 30 seconds using a cardiac-triggered fast gradient hybrid echo-planar or cine SSFP pulse sequences. An inversion preparation pulse is also used which minimizes the signal from myocardium and thus enhances the relative increase in signal intensity produced by the T1-shortening effects of the contrast agent. Because exercise stress cannot be readily done in the MRI scanner, most perfusion studies are performed with vasodilators such as adenosine or dipyridamole. Both qualitative and quantitative analysis have been reported; the latter is done typically by constructing time-intensity curves of myocardial regions and calculating a perfusion reserve index (200,201).

Myocardial Viability. In addition to detection of ischemia, CMR can also be used to differentiate viable from nonviable myocardium. Myocardial delayed enhancement (MDE) imaging, also known as late gadolinium enhancement (LGE) imaging, has become the dominant MRI technique to assess viability (202). It is based on the observation that in necrotic myocardium and in areas where the myocardium is replaced

by collagen (e.g., scar tissue) the washout kinetics of gadolinium-based MRI contrast agents is delayed and its volume of distribution is increased. Consequently, nonviable myocardium appears bright or hyperenhanced compared with viable myocardium when imaged with a segmented inversion recovery fast gradient echo sequence after contrast injection (Fig. 10.21). In practice, MDE imaging is performed 10 to 20 minutes after administration of 0.1 to 0.2 mmol/kg of gadolinium-based contrast. The optimal inversion time is selected using inversion-recovery fast multishot echo-planar imaging, such as a Look-Locker sequence (203). Using this inversion time, MDE is then performed in ventricular short- and long-axis planes.

Several studies in both animals and humans have shown that this technique is effective at identifying the presence, location, and size of acute and chronic myocardial infarction (204–213). Klein, et al. (214) found close agreement between MDE imaging and positron emission tomography (PET) scar size measurements in 31 patients with ischemic heart failure. Because of its superior spatial resolution, MDE is more sensitive than SPECT in patients with small or subendocardial infarctions (215). Most importantly, the transmural extent of MDE can be used to predict improvement in contractile function after revascularization in patients with acute and chronic coronary artery disease (216–219). Another promising clinical application of MDE imaging is detection of myocardial fibrosis in patients with hypertrophic cardiomyopathy (220). Kim et al. (221) demonstrated that the extent of myocardial fibrosis assessed by MDE can be used to stratify risk in these

Figure 10.21. MDE imaging in a 4-year-old patient with Kawasaki disease complicated by coronary artery aneurysms and occlusion of the left circumflex coronary artery. **A:** Short-axis view showing enhancement of the inferior wall (arrow), consistent with transmural myocardial infarction; **B:** Long-axis view showing the base-to-apex extent of the infarct.

patients. Other groups have recently found similar results (222–225). In pediatric and CHD patients, Prakash et al. (191) studied 30 patients with a median age of 13 years (range 0.3 to 40 years) whose diagnoses included repaired CHD in 15, cardiomyopathy in 6, cardiac tumor in 3, dysplastic LV in 2, congenital coronary anomaly in 2, and coronary artery aneurysm following Kawasaki disease in 2. They found good agreement between MRI evaluation of myocardial perfusion and viability and analysis of segmental wall motion, as well as coronary angiography ($n = 10$) and SPECT ($n = 6$). More recently, studies have demonstrated the usefulness of MDE imaging to evaluate endomyocardial scar tissue in patients with systemic RV (193), repaired TOF (192,226,227), endocardial fibroelastosis in hypoplastic left heart syndrome (228), and late after Fontan operation (194).

Diffuse Myocardial Fibrosis. Although contrast-enhanced MDE imaging has been shown to accurately evaluate myocardial necrosis and scar tissue in ischemic and nonischemic heart disease, the technique cannot evaluate diffuse interstitial fibrosis. Several groups have recently developed CMR techniques to measure diffuse myocardial fibrosis based on postgadolinium T1 mapping (29,229–231). Myocardium with more fibrosis will have a higher concentration of gadolinium contrast and thus a shorter T1. Azevedo et al. (232), in a study of 54 adult patients with aortic valve stenosis, demonstrated good agreement between CMR and histologic measurements of diffuse left ventricular fibrosis. Given that this technique holds promise as a noninvasive means to measure diffuse myocardial fibrosis, further studies addressing its accuracy, reproducibility, and clinical usefulness in patients with acquired and CHD are warranted (229).

Tissue Characteristics

Assessment of the myocardium, pericardium, blood vessels wall, and extracardiac tissue for pathologic changes can be valuable in a variety of clinical circumstances. MRI offers a distinct advantage over other modalities for the evaluation of soft tissues because of its ability to discern even minor changes in tissue composition. By manipulations of T1 and T2 weightings and by applying a variety of prepulses or suppression of signals from specific tissue elements such as fat or water, tissue composition can be evaluated. Clinical applications include assessment of myocardial architecture

(e.g., myocardial noncompaction (233,234) and ventricular aneurysm (235,236), evaluation of cardiac and pericardial tumors (Fig. 10.22) (237,238), vessel wall imaging (e.g., aortic dissection (240,241), assessment of the myocardium for fatty infiltration or other pathologic changes (e.g., arrhythmogenic right ventricular cardiomyopathy (242,243), evaluation of the pericardium (e.g., constrictive pericardium (244,245), and assessment of myocardial iron load (245).

In practice, MRI assessment of tissue characteristics is based on the use of several imaging sequences. FSE sequence is used for morphologic imaging of the myocardium, pericardium, blood vessel walls, and extracardiac structures. Manipulations of image contrast (T1, T2, or proton density weighting) and the addition of prepulses (e.g., triple inversion recovery, T2

Figure 10.22. Coronal plane T1-weighted FSE image in a patient with pericardial teratoma (T). Note the compressed RA. LV, left ventricle.

Figure 10.23. MRI assessment of myocardial and liver iron using T2* mapping in a patient with thalassemia major. Note the high signal intensity in the liver and in the left ventricular myocardium, corresponding to high iron concentrations in these organs.

preparation, and fat or water saturation) result in highlighting or suppression of specific tissue characteristics. T2* mapping is used to evaluate myocardial and liver iron concentrations (Fig. 10.23) (246–248). Gradient echo sequences provide information on signal intensity and, more important, on motion of the tissue in question. First-pass myocardial perfusion, early and late enhancement after intravenous administration of gadolinium-based contrast, and myocardial tagging can provide additional diagnostic information about tissue characteristics.

EXAMPLES OF CLINICAL APPLICATIONS OF CMR

Shunt Lesions

Atrial Septal Defect

CMR can be helpful in selected patients with a known or suspected ASD, usually adolescents and adults with inconclusive clinical and echocardiographic findings. For example, CMR provides a noninvasive alternative to transesophageal echocardiography and to diagnostic catheterization in patients with right ventricular volume overload, in whom transthoracic echocardiography cannot demonstrate the source of the left-to-right shunt (249–253). CMR can visualize different types of atrial-level defects, including secundum, primum, sinus venosus, and coronary sinus septal defects. In patients with sinus venosus defect, CMR can provide all the necessary information required for surgical planning. The goals of the CMR examination include delineation of the location and size of the ASD, its relations to key neighboring structures, its size, suitability for transcatheter versus surgical closure, and functional assessment of the hemodynamic burden, including pulmonary-to-systemic flow ratio, and RV size and function.

Although SE sequences have been used to diagnose ASDs, thin structures such as septum primum may not be clearly demonstrated, leading to an overestimation of the defect's

size or to a false positive diagnosis. Cine MRI using SSFP is capable of providing high-quality imaging of the atrial septum and the adjacent anatomic structures, including the vena cavae, pulmonary veins, and the AV valves. The atrial septum is imaged in at least two planes by obtaining a stack of ECG-triggered multiphase SSFP images, a stack in the axial or four-chamber planes, and a stack in an oblique sagittal plane (Fig. 10.24). Additional cine SSFP imaging is performed in the short-axis plane across the ventricles to quantify LV and RV volumes and function. This stack also allows qualitative assessment of RV systolic pressure based on the configuration of the interventricular septum. The septal geometry is concave toward the RV when the RV/LV pressure ratio is low and assumes a flat configuration, or even a concave shape toward the LV, as the RV/LV pressure ratio increases. Interpretation of the hemodynamic significance of septal configuration may be confounded by factors such as inhomogeneous contraction of the RV, intraventricular conduction delay (e.g., right or left bundle branch block, preexcitation), and a high LV pressure.

Measurement of the pulmonary-to-systemic flow ratio (Q_p/Q_s) is clinically helpful in patients with ASD. Several studies have shown that flow measurements in the main pulmonary artery (Q_p) and ascending aorta (Q_s) using VEC MRI agree closely with catheterization-based oximetry (139,153,254,255). In the absence of AV valve regurgitation or an additional shunt, Q_p/Q_s can also be measured by VEC MRI in the ventricular short-axis plane perpendicular to the mitral (Q_s) and tricuspid valve (Q_p) inflows. A third option is to compare the RV and LV stroke volumes obtained by the short-axis cine SSFP. In clinical practice, it is recommended to measure the Q_p/Q_s ratio by more than one method in order to evaluate the data for internal consistency. Flow velocity mapping across the ASD using VEC MRI can be used to further delineate the defect. Color-coded in-plane flow velocity mapping (Fig. 10.24B) or 4-D flow velocity mapping can characterize the flow across the defect (256).

Non-ECG triggered Gd-enhanced 3-D MRA sequence is not ideally suited for evaluation of secundum ASDs due to blurring of thin intracardiac structures. However, this sequence is helpful in the evaluation of sinus venosus septal defects, especially since these defects invariably involve the pulmonary veins (Fig. 10.25).

Ventricular Septal Defect

CMR is rarely used primarily for the evaluation of a VSD. In our experience, only 7 of 1,119 CMR examinations (0.6%) were requested for evaluation of an isolated VSD, primarily for assessment of ventricular dimensions and function and Q_p/Q_s measurement in patients with inadequate or inconsistent echocardiographic data. Many other CMR studies, however, were performed for other indications in patients in whom a VSD was present.

VSDs can be imaged by gradient echo (preferably SSFP) or SE sequences obtained in any combination of planes (Fig. 10.26). The four-chamber plane provides a base-to-apex view of the septum, whereas the short-axis plane images the interventricular septum from anterior–superior to posterior–inferior. Additional imaging in other planes should be performed if the location of the defect and its relation to neighboring key structures (e.g., AV or semilunar valves) is not demonstrated by imaging in standard planes. Measurement of ventricular dimensions and function is a key element of the CMR evaluation in a patient with VSD. Quantification of Q_p/Q_s provides additional hemodynamic information and can be achieved either by VEC MRI flow measurements in the ascending aorta and main pulmonary artery, across the mitral and tricuspid valves, or by comparison of the LV and RV stroke volumes. In the presence of additional shunts (e.g., ASD or PDA) or valve regurgitation, calculation of Q_p/Q_s must be adjusted to account for the effect of the additional flow.

Figure 10.24. Secundum ASD. A: Oblique sagittal SSFP image showing a centrally located defect (arrow); B: Color-coded phase-velocity cine MRI showing flow from the left atrium (LA) to the RA through the defect. LA, left atrium; IVC, inferior vena cava; RA, right atrium; RPA, right pulmonary artery; SVC, superior vena cava.

Patent Ductus Arteriosus

CMR is seldom requested primarily for assessment of an isolated PDA. In several types of complex CHD, evaluation of the ductus arteriosus is an important element of the examination. For example, in patients with TOF and pulmonary atresia, the

ductus arteriosus can be an important source of pulmonary blood supply (257,258). Gd-enhanced 3-D MRA is a particularly helpful imaging technique in these patients because it allows accurate delineation of all sources of pulmonary blood supply, including a PDA, aortopulmonary collateral vessels, and the central pulmonary arteries (259). Another clinical circumstance in which MRI evaluation of a PDA may be requested is the adult with CHD in whom limited acoustic windows can hamper echocardiographic evaluation. Imaging of a PDA can be accomplished by several MRI sequences (Fig. 10.27). If a PDA is detected, it is vital to also evaluate the direction of flow across the duct by VEC MRI, to assess the hemodynamic burden by measurements of ventricular volumes and function, to measure the Q_p/Q_s , and to assess RV pressure by septal position in the short-axis plane.

Figure 10.25. Maximal intensity projection Gd-enhanced 3-D MRA showing drainage of right pulmonary veins (RPVs) to the cardiac end of the right superior vena cava (RSVC) in a patient with sinus venosus defect and bilateral superior vena cavae. LSVC, left superior vena cava.

Anomalies of the Aorta

Coarctation of the Aorta

The use of MRI to image anomalies of the aortic arch dates back to the early 1980s (260). While those studies provided mostly static anatomical information, the advent of new imaging sequences has greatly expanded the diagnostic capabilities of CMR to include comprehensive anatomic and functional evaluation. In adults with CHD, Therrien et al. (261) have shown that the combination of clinical assessment and MRI provides a better “cost-effective” yield compared with a combination that relies on echocardiography as the primary imaging modality. Others have shown the utility of CMR in infants and children with coarctation and other anomalies of the aortic arch (176,262,263).

The objectives of the CMR evaluation of suspected or repaired aortic coarctation include (a) detailed imaging of the aorta including the proximal brachiocephalic arteries and the descending aorta to the level of the renal arteries; (b) imaging of blood flow throughout the thoracic aorta to detect high-velocity flow jets suggestive of stenosis; (c) detection of collateral vessels that bypass the coarctation site; (d) assessment of

Figure 10.26. ECG-triggered, breath-hold, cine SSFP imaging of VSD. A: Small membranous VSD (arrow); B: Large muscular VSD (arrow).

left ventricular mass, volumes, and function; and (e) detection of any associated lesions.

Much of the anatomic information is gleaned from the Gd-enhanced 3-D MRA, including the anatomy of the aorta, imaging of collateral vessels, and cross-sectional measurements of the aorta in various locations (Fig. 10.28). A 3-D SSFP sequence provides an alternative to contrast MRA when an intravenous cannula cannot be placed or if there is a contraindication to the use of Gd. A SE sequence with double inversion recovery provides high-resolution imaging of the

aortic wall. This may be particularly important in cases with discrete coarctation comprised of a thin “shelf” that protrudes into the aortic lumen and in patients with atypical location of the coarctation such as in the abdomen (Fig. 10.29). Gradient echo sequences are helpful for detection of signal void due to high-velocity turbulent jets.

Evaluation of the hemodynamic significance of coarctation is an important element of the CMR examination. Several investigations compared the anatomic features and the extent of collateral blood flow with coarctation diameter measured

Figure 10.27. MRI evaluation of PDA. A: Cine SSFP in an oblique sagittal plane showing small PDA; B: Color-coded cine phase velocity MRI showing flow from the aortic isthmus (Ao) to the main pulmonary artery (MPA).

Figure 10.28. Gadolinium-enhanced 3-D MRA in patients with severe aortic coarctation. **A:** Maximal intensity projection; **B:** 3-D volume rendering showing prominent internal mammary arteries (*arrow*) and collateral vessels to the descending aorta (*arrowheads*).

by x-ray angiography (262,263), blood pressure measurements by sphygmomanometry (264), and Doppler assessment of flow velocity (265). Riquelme et al. (266) showed a correlation coefficient of 0.99 between gradient echo cine MRI measurement of coarctation diameter and angiography. Simpson et al. (262) and Mendelsohn et al. (263) reported correlation coefficients of 0.9 and 0.91, respectively. Other groups have focused on the percent increase in descending aorta flow from collateral vessels to assess CoA severity. Steffens et al. (267) reported that the percent increase in flow correlated with the

diameter of the CoA segment ($r = 0.94$), with arm-to-leg blood pressure difference ($r = 0.84$), and with Doppler gradient ($r = 0.76$). More recently, Araoz et al. (264) demonstrated that the percent increase in descending aorta flow in 19 patients with repaired coarctation more accurately reflected the degree of narrowing than arm-to-leg blood pressure measurements. We have developed a CMR-based model to predict the probability of hemodynamically significant coarctation defined as a pressure gradient ≥ 20 mm Hg measured by catheterization (268). The combination of the smallest cross-sectional area of the

aorta (measured from the Gd-enhanced 3-D MRA) and the heart rate-adjusted mean deceleration of flow in the descending aorta (measured by VEC MRI distal to the CoA) (Fig. 10.30) predicted coarctation severity group with 95% sensitivity, 82% specificity, 90% positive and negative predictive values, and an area under the receiver-operator characteristics curve of 0.94. Muzzarelli et al. (269) recently demonstrated that the optimal location for assessing the flow profile in the descending aorta is at the level of the diaphragm.

Aortic Aneurysm and/or Dissection

Severe dilation, aneurysm formation, and dissection can complicate the course of some congenital cardiac defects such as bicommissural aortic valve and TOF, and are common in patients with Marfan syndrome and other connective tissue disorders. CMR is an ideal modality for longitudinal noninvasive assessment of the aorta, especially in adolescents and adults in whom the echocardiographic windows are often limited. In contrast to CT, CMR does not expose the patients to the risks of ionizing radiation and can also provide functional information such as measuring aortic regurgitation fraction and left ventricular dimensions and function. In patients with suspected acute dissection who may require emergent intervention, CT angiography might be more readily available.

The imaging strategy for assessment of aortic aneurysm is modified from the protocol used for aortic coarctation. Both spin and gradient echo sequences are acquired in planes perpendicular and parallel to the long-axis of the aorta (Fig. 10.31A). The branch vessels of the aorta are also examined

to determine for extension of an aneurysm, dissection, or obstruction. A stack of thin-sliced ECG-triggered SSFP cine is acquired perpendicular to the aortic root and ascending aorta. This sequence allows accurate measurements of orthogonal dimensions of the dilated aortic segment during systole. In addition, the aortic wall is examined in detail for evidence of dissection and VEC MRI is used to evaluate aortic valve function. This technique can also be used to distinguish between flow in the true and false lumen of aortic dissection. Gd-enhanced MRA is particularly helpful for evaluation of tortuous aortic segments and branch vessels (Fig. 10.31B).

Vascular Rings and Pulmonary Artery Sling

Vascular rings constitute an uncommon form of congenital vascular anomaly in which the trachea and esophagus are encircled completely by vascular structures. Rings are formed by abnormal persistence and/or regression of components of the aortic arch complex. MRI is ideally suited for evaluation of vascular rings and LPA sling because it provides good visualization of the airways and the vasculature, imaging can be performed in any plane, and there is no exposure to ionizing radiation (270,271). The main drawback of MRI is the need for sedation given that most patients with vascular rings are too young to cooperate. Although vascular rings account for fewer than 1% of patients with CHD, they account for 10% of all CMR examinations in our laboratory in patients younger than 1 year of age (272). Although multirow detector CT with contrast can provide excellent imaging of the airways and vasculature, this technique is associated with a significant exposure to ionizing radiation.

Figure 10.31. Large aneurysm of the descending aorta in a patient with connective tissue disorder who underwent replacement of the ascending aorta and transverse arch. **A:** SSFP cine MRI in multiple planes; **B:** Volume rendered reconstruction of Gd-enhanced 3-D MRA. The left panel shows an anterior view and the right panel shows a posterior view.

On the other hand, the potential ability of CT to obtain good quality images without general anesthesia and endotracheal intubation is advantageous (see Chapter 11).

MRI evaluation of vascular rings and left pulmonary artery sling can be accomplished by a combination of SE, free-breathing isotropic 3-D SSFP, and Gd-enhanced 3-D MRA (Fig. 10.32A). Thin (2 to 3 mm) contiguous FSE with double inversion recovery slices provide excellent visualization of the

trachea, main stem bronchi, and the vasculature. In addition to the axial plane, imaging of the trachea in oblique coronal and sagittal planes parallel to its long axis can be helpful. Occasionally, FSE imaging may not be able to distinguish stenotic from atretic aortic segments with confidence. Gd-enhanced 3-D MRA can be used to determine if any segment of the vascular ring does not have luminal continuity and is ideally suited for 3-D reconstruction (Fig. 10.32B).

Figure 10.32. Vascular ring consisting of a double aortic arch. **A:** FSE with double inversion recovery sequence in the coronal plane showing tracheal compression and cross-sections of the larger right and the smaller left arches; **B:** Volume rendered reconstruction of Gd-enhanced 3-D MRA. The left panel shows a posterior view and the right panel shows a superior view.

Pulmonary Artery Anomalies

Most anomalies of the pulmonary arteries occur in association with other CHD. For example, stenosis, hypoplasia, and/or discontinuity of the branch pulmonary arteries are commonly associated with TOF. Congenitally absent branch pulmonary artery without additional CHD is a rare anomaly. It is characterized by absence of the mediastinal pulmonary artery on the opposite side of the aortic arch in most cases (Fig. 10.33) (273). A ligamentum arteriosum can usually be found between the base of the subclavian artery and peripheral pulmonary arteries at the hilum of the ipsilateral lung. Early diagnosis and establishment of vascular continuity between the main pulmonary artery and the peripheral branches on the affected side may promote growth of the pulmonary vascular bed and reduce the likelihood of complications. Another condition where a branch pulmonary artery is absent is agenesis of the corresponding lung. In contrast to congenitally absent branch pulmonary artery without associated anomalies, in agenesis of a lung, the ipsilateral pulmonary veins are absent as well.

Other rare anomalies of the branch pulmonary arteries include origin from the ascending aorta (so-called hemitruncus) and crossed pulmonary arteries.

Spin and gradient echo cine sequences can be used to assess the central pulmonary arteries but these techniques may have a limited ability to depict very small and tortuous vessels, especially in infants (see discussion on MRI evaluation of pre-operative TOF). Gd-enhanced 3-D MRA provides excellent depiction of the pulmonary arterial tree, including the second- and third-generation branches. This sequence has been shown to image pulmonary arterial branches as small as 1 mm even in the absence of antegrade blood flow, as is the case in congenitally absent branch pulmonary artery without associated anomalies (Fig. 10.29) (259).

Systemic and Pulmonary Venous Anomalies

Although referral to CMR primarily for evaluation of the pulmonary veins accounts for only 3.4% of cases in our hospital, evaluation of the systemic and pulmonary veins is integral

Figure 10.33. Congenitally absent right pulmonary artery. A: Axial (transverse) view of a cine MRI showing a dilated left pulmonary artery (LPA) and absence of a right pulmonary artery behind the ascending aorta (AAo) and superior vena cava (SVC); B: Subvolume maximal intensity projection Gd-enhanced 3-D MRA in the coronal plane. Note the ductal dimple at the base of the right innominate artery (*asterisks*) and the markedly hypoplastic distal right pulmonary artery at the hilum of the right lung (*arrow*); C: Aortopulmonary collateral vessels to the right lung.

Figure 10.34. Volume rendered reconstruction of Gd-enhanced 3-D MRA in a patient with partially anomalous pulmonary venous connection of the left upper pulmonary vein (arrow) to the left innominate vein.

to a comprehensive CMR evaluation in patients with CHD. Venous anomalies are often associated with other CHD and unsuspected, but clinically important, abnormalities can be detected on examinations performed for other indications. Gd-enhanced 3-D MRA is particularly helpful for anatomic evaluation of systemic and pulmonary venous anomalies (Fig. 10.34) (58,274). Gradient echo sequences can be used to depict an abnormal blood flow pattern such as a turbulent jet. A FSE sequence can be used to provide high-resolution imaging of vessel wall, such as in patients with pulmonary veins stenosis. VEC MRI is used to measure blood flow in selected vessels to assess regional blood flow (274). Applications include measurement of Q_p/Q_s , the fractional flow to each lung in patients with pulmonary veins stenosis, and the direction of flow in the azygous vein in a patient with narrowing of the superior vena cava.

Tetralogy of Fallot

TOF is the most frequent diagnosis among patients referred for CMR evaluation at Children's Hospital Boston (Table 10.1). Unlike infants in whom echocardiography generally provides all the necessary diagnostic information for surgical repair (258,275), MRI assumes an increasing role in adolescents and adults with TOF in whom the acoustic windows are frequently limited (160). CMR is useful in both preoperative and postoperative assessment of TOF, but the focus of the examination is different.

Preoperative MRI

In most patients with unrepaired TOF, the central question for the CMR examination is to delineate all sources of pulmonary blood flow—pulmonary arteries, aortopulmonary collateral

vessels, and the ductus arteriosus. Several studies have shown that SE and 2-D gradient echo cine MRI techniques provide excellent imaging of the central pulmonary arteries and major aortopulmonary collaterals (257,276). However, these MRI techniques require relatively long scan times for complete anatomical coverage, and small vessels (<2 mm) may not be detected. Furthermore, these 2-D techniques are not optimal for imaging long and tortuous blood vessels. Gd-enhanced 3-D MRA is ideally suited to image these vessels (Fig. 10.35). Compared with conventional x-ray angiography, MRA has been shown to be highly accurate in depicting all sources of pulmonary blood supply in patients with complex pulmonary stenosis or atresia, including infants with multiple small aortopulmonary collaterals (259).

Cine SSFP is used to assess ventricular dimensions and function, the right ventricular outflow tract (RVOT) as well as dynamic flow imaging of valve function. When the origins and proximal course of the left and right coronary arteries are not known from other imaging studies, they should be imaged either by a coronary MRA sequence or by a FSE sequence in the axial or aortic root short-axis planes. Particular attention is paid to the exclusion of a major coronary artery crossing the RVOT.

Postoperative MRI

CMR has been used extensively for assessment of postoperative TOF patients of all ages, but its greatest clinical utility is in adolescents and adults (168,277,278). Many studies have shown that the degree of pulmonary regurgitation measured by VEC MRI is closely associated with the degree of RV dilation (149,279–281). Another factor that affects RV function is the presence and extent of an aneurysm in the RVOT (226,282). Quantitative assessment of RV and LV dimensions and function is a key element of CMR evaluation in patients with repaired TOF (Fig. 10.36) (64). The degree of RV dysfunction is an important determinant of clinical status late after TOF and is also closely associated with LV function, likely through ventricular–ventricular interaction (283,284). Taken together with clinical assessment and electrophysiologic data, information derived from CMR on pulmonary regurgitation fraction, RV and LV dimensions and function, presence and extent of a RVOT aneurysm, and presence of branch pulmonary artery stenosis is used to direct clinical care in patients with repaired TOF (192,278,285–287).

The goals of the CMR examination, therefore, include quantitative assessment of left and right ventricular volumes, mass, stroke volumes, and ejection fraction; imaging the anatomy of the RVOT, pulmonary arteries, aorta, and aortopulmonary collaterals; and quantification of pulmonary regurgitation, tricuspid regurgitation, pulmonary-to-systemic flow ratio, and detection of scar tissue, especially in the RVOT. CMR examination protocols for evaluation of repaired TOF have been published (277,278).

Transposition of the Great Arteries

CMR is seldom requested for preoperative assessment of infants with D-loop TGA because echocardiography usually provides all necessary diagnostic information (288). In postoperative TGA, CMR assumes an increasing role due to its ability to noninvasively evaluate most clinically relevant issues (124,193,289–291).

Postoperative Atrial Switch (Senning or Mustard Operation)

The goals of CMR evaluation of postoperative atrial switch include (a) quantitative evaluation of the size and function of the systemic RV (Fig. 10.36A) (292); (b) imaging of

Figure 10.35. Subvolume maximal intensity projection Gd-enhanced 3-D MRA showing aortopulmonary collateral vessels (*arrows*) in a newborn with TOF and pulmonary atresia. **A:** Coronal plane; **B:** Axial (transverse) plane.

the systemic and pulmonary venous pathways for obstruction and/or baffle leak(s) (Fig. 10.36B); (c) assessment of tricuspid valve regurgitation; (d) evaluation of the left and right ventricular outflow tracts for obstruction; (e) detection of aortopulmonary collateral vessels and other associated anomalies; (f) evaluation of the coronary arteries (293); and (g) detection of myocardial fibrosis and/or scar tissue (193,293). The response of the systemic RV to pharmacologic stress (dobutamine) or to exercise can be tested by CMR, but the clinical utility of this information awaits further study (125,289).

Postoperative Arterial Switch

The long-term concerns in patients after the ASO relate primarily to the technical challenges of the operation—transfer of the coronary arteries from the native aortic root to the neo-aortic root (native pulmonary root) and the transfer of the pulmonary arteries anterior to the neoascending aorta. Consequently, the goals of CMR evaluation of postoperative arterial switch include (a) evaluation of global and regional LV and RV size and function; (b) evaluation of the left and right ventricular outflow tracts for obstruction; (c) qualitative estimation of RV systolic pressure based on the configuration

Figure 10.36. Short-axis, ECG-triggered, breath-hold, cine SSFP imaging in a patient with TOF, severe pulmonary regurgitation, and markedly dilated RV.

Figure 10.37. ECG-triggered, breath-hold, cine SSFP imaging in a patient with Mustard palliation of D-loop TGA. A: Short-axis view showing the dilated and hypertrophied RV, which compresses the thin-walled LV; B: Baffle leak (arrow) with flow from the pulmonary venous chamber (PVC) to the systemic venous chamber.

of the interventricular septum; (d) imaging of the great vessels with emphasis on evaluation of the pulmonary arteries for stenosis and the aortic root for dilation (Fig. 10.38); (e) detection of aortopulmonary collateral vessels and other associated anomalies; (f) evaluation of the origins and proximal course

of the coronary arteries (51,294); and (g) detection of myocardial ischemia, fibrosis, and/or scar tissue (290). The role of myocardial perfusion and viability imaging in this population deserves further study, especially with regard to the sensitivity, specificity, and predictive values of these techniques for detection of myocardial ischemia and the prognostic implications of myocardial fibrosis and/or scar tissue detected by delayed myocardial enhancement.

Single Ventricle and Fontan

Before Stage I Palliation

CMR has an important role in the diagnostic evaluation and follow-up of patients with anatomic and functional single ventricle. Echocardiography is the primary imaging tool during the initial evaluation since most patients present in the newborn period or early infancy and their acoustic windows are typically adequate. CMR is used before the first palliative procedure only in selected cases, usually to evaluate incompletely diagnosed extracardiac anatomy such as anomalies of the aortic arch, pulmonary arteries, and venous anomalies.

Before Stage II Palliation

The role of CMR increases after the first palliative surgical procedure. CMR may be requested to assess potential complications or sequelae of the first operation such as residual or recurrent aortic arch obstruction, stenosis or compression of branch pulmonary arteries or pulmonary veins, aortopulmonary or ventriculopulmonary shunts, airway compression, and others. In patients who are candidates for a bidirectional Glenn shunt or a hemi-Fontan procedure (second-stage palliation), CMR can substitute routine diagnostic catheterization in selected patients (295). Evidence from two retrospective studies suggests that in a substantial number of patients who are candidates for a second-stage palliation cardiac catheterization data do not change the surgical plan (296,297). Although some of these patients undergo a concomitant transcatheter intervention (e.g.,

balloon dilation of coarctation or coil occlusion of aortopulmonary collaterals), the indications for and the clinical benefits from such procedures are not clearly defined. Whereas echocardiography can provide much of the anatomic and functional information in these patients, there are circumstances in which parts of the anatomy may not be fully defined and additional quantitative functional data may be desired. CMR can potentially fulfill these goals (Fig. 10.39). Brown et al. (298) in a prospective randomized clinical trial

of CMR versus routine catheterization showed that CMR is a safe, effective, and less costly alternative to routine catheterization in the evaluation of selected patients before bidirectional Glenn operation. Another retrospective analysis showed that a noninvasive diagnostic algorithm effectively screened for patients who are unsuitable for a Fontan operation and that omission of routine preoperative hemodynamic assessment at catheterization did not impair prediction of adverse postoperative outcomes (299).

Figure 10.39. MRI evaluation of hypoplastic left heart syndrome after stage I palliation. **A:** Volume rendered reconstruction of Gd-enhanced 3-D MRA showing the RV-to-pulmonary artery conduit (*arrow*) and the arterial anastomoses; **B:** maximal intensity projection of a modified right Blalock-Taussig shunt (BTS); **C:** maximal intensity projection image in the axial (transverse) plane showing the branch pulmonary arteries; **D:** maximal intensity projection image showing the anastomosis between the main pulmonary artery and the native ascending aorta; (*Continued*)

Figure 10.39. (Continued) E: maximal intensity projection image of the reconstructed aorta showing mild coarctation (arrow). AAo, ascending aorta; DAo, descending aorta; LPA, left pulmonary artery; MPA, main pulmonary artery; RIA, right innominate artery; RPA, right pulmonary artery.

The goals of the CMR examination in patients who are candidates for a second-stage palliation include the following: (a) anatomy of the systemic and pulmonary veins; (b) anatomy of the branch pulmonary arteries; (c) anatomy of the thoracic aorta with an emphasis on exclusion of arch obstruction; (d) presence and distribution of aortopulmonary and venous collaterals, including quantification of collateral flow (174,175); (e) quantitative assessment of systemic ventricular function; (f) quantitative assessment of valve regurgitation; (g) evaluation of the atrial septum for restriction; and (h) detection of myocardial fibrosis or scar tissue (228).

Before and after Fontan Palliation

The role of CMR in the evaluation of patients before and after the Fontan operation is growing (300). Several investigators explored the use of clinical criteria and noninvasive imaging to supplant routine cardiac catheterization in low-risk patients before a Fontan operation (299,301,302). These studies noted that a substantial proportion of patients can undergo surgery without a preceding catheterization and emphasized the role of CMR. After Fontan, CMR is increasingly used for surveillance of late complications (198,303). Several reports have used CMR as an investigational tool to study blood flow dynamics within the Fontan pathways and to delineate the distribution of inferior and superior caval flow to each lung (171,172,186,187,303,304). Myocardial tagging has proved an important investigational tool in the evaluation of myocardial mechanics in patients with functional single ventricle and Fontan circulation, demonstrating asynchrony and impaired regional wall motion (117). Cine SSFP is the preferred method for assessment of ventricular

Figure 10.40. Subvolume maximal intensity projection image of Fontan pathway in a patient with atriopulmonary anastomosis. A: Oblique sagittal view showing the atriopulmonary anastomosis (curved arrow); B: Oblique transverse view showing the atriopulmonary anastomosis and branch pulmonary arteries. Ao, aorta; LPA, left pulmonary artery; PAs, pulmonary arteries; RPA, right pulmonary artery.

size and function (305) and LGE imaging is used for assessment of myocardial scar (194).

The goals of the CMR examination in patients with the Fontan circulation include (a) assessment of the pathways from the systemic veins to the pulmonary arteries for obstruction and a thrombus (Fig. 10.40); (b) detection of Fontan baffle fenestration or leaks; (c) evaluation of the pulmonary veins for compression; (d) measurements of systemic ventricular volumes, mass, and function; (e) detection of myocardial fibrosis; (f) imaging of the systemic ventricular outflow tract for obstruction; (g) quantitative assessment of the AV and semilunar valve(s) for regurgitation; (h) imaging the aorta for obstruction or an aneurysm; (i) measurement of aortopulmonary collateral flow; and (j) detection of systemic venous or systemic-to-pulmonary venous collateral vessels.

An important limitation of CMR in patients with Fontan circulation is the frequent presence of metallic implants (e.g., stainless steel coils, stents, occluding devices) that produce image artifacts. Garg et al. (60) reviewed the CMR studies of 120 consecutive CMR examinations from 1996 to 2003 and found that artifacts from metallic implants were present in 54% of the studies. Major artifacts (mostly caused by stainless steel coils) were present in 36% of patients, and in 20% the artifact precluded complete volumetric assessment of the systemic ventricle. More recently, however, use of nonferromagnetic coils has greatly reduced the frequency imaging artifacts in patients with Fontan circulation. CT can be used as an alternative to CMR in patients with large image artifacts as well as in those with relative contraindications to CMR (e.g., pacemaker).

Cardiac Computed Tomography in Children with Congenital Heart Disease

Frederick R. Long ■ Joachim G. Eichhorn

INTRODUCTION

Computed tomography (CT) and magnetic resonance imaging (MRI) are advanced imaging techniques that can provide 3-D representations of cardiovascular anatomy and functional hemodynamic information that is not limited by field of view or acoustic window as can occur with echocardiography, the primary modality for imaging children with congenital heart disease (CHD). Thus, CT and MRI are supplementary examinations to echocardiography that may substitute the need for more invasive catheter angiography (1–4). The most common clinical indications for CT are to evaluate the extracardiac vascular anatomy (thoracic, coronary, and pulmonary artery and vein connections). In addition, CT and MRI can provide quantitative hemodynamic information that is more accurate and reproducible than echocardiography in following disease progression and timing intervention in children with CHD (5,6).

Assuming equal expertise and access to state-of-the-art hardware, the choice of whether to perform a CT or MRI exam depends upon the unique advantages or disadvantages of CT versus MRI for each individual patient (Table 11.1). Due to the theoretical risk of ionizing radiation in causing cancer, which is greater in infants and children than in adults, MRI is the preferred exam when all other considerations are equal (7). The chief advantages of CT over MRI are much shorter examination times, 2 to 15 seconds versus 30 to 45 minutes, and greater spatial resolution, $0.4 \times 0.4 \times 0.4$ mm versus $0.9 \times 1.1 \times 1.2$ to 2.4 mm (8,9).

The short examination time may preclude the need for sedation. Thus, CT may be preferred in critically ill infants who may not tolerate a longer MRI procedure or who can be examined without sedation or in emergent situations such as in the evaluation of suspected aortic dissection (10). Because of the better spatial resolution, CT may be preferred to image small structures such as the coronary arteries or the small vascular structures in newborns and infants (Figs. 11.1 and 11.2). CT is the modality of choice for imaging the lung parenchyma and airways, to evaluate peripheral pulmonary artery and vein stenosis, and pulmonary emboli (6). Of course, CT should replace MRI in patients with metallic clips, coils, and stents that are not proven safe for MRI or result in unacceptable degradation of MR image quality due to magnetic susceptibility artifacts. MRI is specifically contraindicated in patients with pacemakers or defibrillators. MRI is the modality of choice for quantifying ventricular volumes and function, blood flow, and myocardial perfusion and viability (6).

METHODS AND TECHNIQUE

CT Angiography (CTA) Protocol

Both CT and MRI can be considered advanced imaging techniques not only because of the highly detailed 3-D diagnostic information that they provide but also because their successful

performance requires special expertise and careful technique. The CTA protocol includes a number of factors: patient preparation and positioning, whether ECG-gating or sedation is used; the amount, rate, and timing of intravenous contrast injection; and other parameters such as pitch, slice thickness, and radiation exposure settings. All of these factors are highly dependent on the type of scanner used and the size of the patient (11). In general, a 0.5- to 1.2-mm collimation or slice thickness with a pitch of 1 to 1.5 is used with 8–320 detector scanners to maximize spatial resolution (11). Other major factors are described in detail below.

Sedation and Controlling Respirations

Motion of any kind creates artifacts and blurring that degrade images. In infants and young children, the inability to hold still and to breath hold may significantly degrade image quality. A child may suddenly move, start crying, or just suddenly take in a big breath, particularly during contrast injection. Fast scan speeds cannot compensate for such gross movements.

In infants and young children who are free-breathing and who do not make sudden movements, the fast scan speeds using 8- to 16-slice or greater multidetector scanners can usually compensate for respiratory motion. Adequate chest CTA studies have been reported in free-breathing infants using only oral or rectal sedation or without any sedation. Some institutions report acquiring successful CT exams in neonates without sedation by feeding the infant and wrapping him/her in a blanket (12). The possibility to perform the exam without sedation represents a major potential advantage of CT over MRI.

In general, we sedate our pediatric patients with CHD with the assistance of general anesthesia. This level of support optimizes the safety of our patients who tend to be high-risk infants with complex CHD and who may be hemodynamically unstable. At the same time, image quality is optimized by ensuring that the patient will remain still.

Other advantages of anesthesia assistance include the ability to acquire the CT examination at optimized inspiratory and expiratory lung volumes, depending on the indication. In general, the vascular anatomy is better displayed during an inspiratory breath hold. Exams done during an expiratory breath hold are used to evaluate for tracheomalacia, bronchomalacia, and air trapping. In addition, anesthesia assistance can make intravenous access nontraumatic to the child. IV access is often difficult in infants with CHD as in other sick children. With anesthesia assistance, the IV can be placed after inhalation induction that has the benefit of having a vasodilatory effect (13).

Anesthesiologists also have access to very short-acting sedative drugs (sevoflurane, propofol, and remifentanyl) that are better suited for the short duration of a CT scan (13). In addition, by using short-acting drugs, endotracheal intubation can

be avoided by providing facemask ventilation. Breath holding can be achieved while performing facemask ventilation using controlled ventilation technique (14,15). Controlled ventilation involves positive-pressure face mask hyperventilation to induce a transient respiratory pause. During an induced breath hold, we apply positive airway pressure of 15 to 25 cm water pressure to inflate the lungs. By titrating short-acting agents so that spontaneous respirations are not completely suppressed, atelectasis, or partial/complete collapse of the lung, can be minimized. Endotracheal intubation with complete

Figure 11.1. An 8-month-old boy with type B interrupted aortic arch after Damus-Kaye-Stansel anastomosis, aortic arch repair, pulmonary homograft, and aortic stent placement (two “overlapping” stents in blue). Three-dimensional volume-rendered images shown were acquired during controlled ventilation with deep conscious sedation on an eight-slice MDCT following 25 mL contrast by hand injection. The 6-second scan demonstrates in a single shot the following relevant information (in order from *top to bottom, left to right*): correct position of the stent, mild left subclavian artery stenosis, left ventricle (LV) outflow tract to the native aorta, LV outflow tract to the neo-aorta (Neo-Ao) (appreciate the small ventricular septal defect marked by the *arrow*) and coronary arteries (*small arrows*). Ao, aorta; LA, left atrium; LPA, left pulmonary artery; MPA, main pulmonary artery; PV, pulmonary vein; RPA, right pulmonary artery; RV, right ventricle; SVC, superior vena cava.

suppression of spontaneous respirations often results in large areas of dependent atelectasis that may obscure vascular anatomy, especially the assessment of the pulmonary veins.

Intravenous Contrast Injection

The usual dose of intravenous iodinated contrast media is 2 mL/kg with an iodine concentration of 240 to 370 mg/mL. The greater the iodine concentration, the better the vascular enhancement, but this also increases the contrast viscosity. Nonionic contrast media is used exclusively to decrease the risk of anaphylaxis, contrast-induced nephropathy, gastrointestinal upset, and complications from potential contrast extravasation into the soft tissues (11,16,17).

CTA image quality is critically dependent on the level of aortic enhancement that requires adequate delivery and timing of the intravenously administered bolus of iodinated contrast media. In general, the more rapid the rate of contrast injection, the greater will be the level of vascular enhancement. The degree of enhancement is inversely related to body weight (17), which is an advantage when imaging small infants.

Contrast injection rate is limited by the size and location of the peripheral intravenous line. The antecubital location is the preferred location due to larger vein size. If this site is not feasible, a forearm/hand vein and foot vein are alternatives. When possible, the right upper extremity should be used to limit streak artifact across the aortic arch (11).

The optimal injection rate for CTA is 1 to 5 mL/s depending on the age of the patient and indication. For example, injection rates of 1 mL/s are sufficient for studies in infants and can be obtained by hand injection through a 24-gauge angiocatheter (12). Rates of ≥ 2 mL/s, which are optimal for older infants and young children, require the use of a power injector and at least a 22-gauge peripheral angiocatheter (Fig. 11.3). Rates of 3 to 5 mL/s require a 20-gauge catheter (18,19). Rates of approximately ≥ 5 mL/s are usually used for coronary artery evaluation or to detect pulmonary emboli in adult-sized patients (20).

The use of indwelling central venous and percutaneously inserted central catheter (PICC) lines for contrast injection is in general avoided because the lines limit contrast injection rates to ≤ 1 mL/s as per manufacturing guidelines (21). Power PICC lines that are designed to be power injected are exceptions to this rule. Umbilical venous catheters (UVC) have been used when peripheral venous access is not possible. A potential problem could arise if the UVC line terminates in an occluded ductus venosus (12). Diagnostic CTA exams can be performed, although with difficulty, while a patient is treated with extracorporeal membrane oxygenation (22).

Timing of the Contrast Bolus

The objective is to synchronize imaging with the delivery of the bolus of intravenous contrast when the region of interest is at its peak of enhancement. Various methods of timing have been used and include automated bolus tracking, the use of a precontrast test bolus, and empiric methods (17). In older children and adults, almost any method will work well, but in infants, it is much more difficult due to the greater potential differences in cardiac output and the small size of the contrast bolus. For example, in infants, the test bolus may be the size of the study bolus, and bolus tracking may be limited by the post trigger delay in scan initiation. When injecting a small amount of contrast for infants weighing <10 kg, the delay from the start of injection to start of scanning can be empirically estimated by the circulation time of 12 to 15 seconds. When injecting a large amount of contrast in an adult-sized patient, empirically starting the scan at the end of contrast injection should capture near peak aortic enhancement (17).

Figure 11.2. A 3-kg newborn with heterotaxia and total anomalous pulmonary venous drainage to the portal vein. Three-dimensional volume-rendered images obtained on a 64-slice MDCT scanner following hand injection of 6 mL of contrast in the UVC. **A:** Images (right to left and top to bottom) show the aortic valve (arrows) and ventricular septal defect (VSD) as well as a ductus and MAPCAs arising from the aorta to supply the lung and the pulmonary arteries. **B:** Image shows the confluence of the pulmonary veins (PV) draining across the diaphragm to the liver. Appreciate the size of <1 mm of the PV. Ao, Aorta; HV, hepatic veins; RA, right atrium; LV and RV, left and right ventricle.

Figure 11.3. A 5-month-old boy with pulmonary stenosis (arrow). Coronal reformatted MIP image obtained using a 22-gauge IV in left hand at 2 mL/s by power injector (20 mL Optiray 320) using a 64-slice MDCT. Contrast enhancement exceeded 600 HU.

A method that utilizes the contrast-covering time concept makes use of the advantages of bolus tracking but compensates for the trigger delay by adjusting the injected flow rate of contrast. This requires a dual power injector (9).

In patients who have undergone a Fontan procedure, the lack of proper contrast mixing in the right atrium due to the sluggish, slow blood flow through the Fontan circuit often results in suboptimal contrast enhancement of the pulmonary arteries and may mimic a thrombosis. By employing simultaneous injections of contrast in both upper- and lower-extremity veins and by monitoring enhancement of the pulmonary arteries by using bolus tracking, this problem can be minimized (23). One may need to be ready to perform a delayed second-phase CT scan if the dual injection method is unsuccessful. Because intravascular contrast enhancement persists longer when using gadolinium and MRI, evaluation of Fontan anatomy is easier with MRI (24).

Radiation Protection

In part because of the success and proliferation of CT for medical imaging, safety concerns regarding the potential hazards of ionizing radiation from frequent and indiscriminate use of diagnostic CT examinations have in recent years come to the forefront. Because of the uncertainty of what risks, if any, can be attributed to repeated exposures of low levels of ionizing radiation used for medical imaging, a conservative approach has been adopted by health professionals to limit radiation exposure as low as reasonably achievable (ALARA) (7,25).

Dose Reduction – a multifactorial issue

Figure 11.4. Dose reduction—a multifactorial issue.

The radiation exposure from a given exam is influenced by many factors (Fig. 11.4): the type of scanner, for example, dual source, electron beam etc.; the vendor of the scanner; the use of shielding; the use of dose modulation software; the kilovolt potential (kVp); tube current or milliamperes (mA); collimation; rotation speed and pitch; and whether ECG or other type of gating is used (26). There are a number of suggested ALARA protocols in the literature (9,11,12).

The radiation dose received is proportional to the square root of the kilovolt potential (kVp) and is directly related to tube current or milliamperes (mA) times the duration of exposure (seconds). Because of the reduced x-ray attenuation secondary to lower body mass in children, the exposure settings can be reduced without loss in image quality (Figs. 11.5 and 11.6). When intravenous contrast is used, a lower kVp is advantageous in that it accentuates the beam absorption properties of the high atomic weight of iodine (16). Reducing the kVp to 80 in infants and small children thus allows reduction in dose while at the same time enhancing vascular contrast. The ALARA principle dictates that the milliamperes used should be adjusted according to patient weight (27).

The estimated effective doses of CTA using pediatric ALARA protocols in infants ranges from 1.1 to 1.7 mSv using nongated and 2.2 to 3.4 mSv for gated multidetector computed tomography (MDCT) (9). With a dual-source scanner, effective doses for gated and nongated CT are <1 mSv. To put these radiation dose exposures in perspective, the average natural background dose for living 1 year in Ohio is estimated to be 3 mSv and in Germany 2.3 mSv.

Electrocardiograph Gating

A non-ECG-gated acquisition is optimal for most CT exams in CHD, which are obtained to evaluate the extracardiac vasculature. Not only is there no radiation dose penalty but also nongated exams are faster and extracardiac structures are more susceptible to respiratory motion than cardiac pulsation artifact.

With the fast temporal resolution of 165 ms using 64-slice MDCT, electrocardiographic (ECG) gating is possible. Retrospective ECG gating is necessary for a comprehensive evaluation of the coronary arteries and allows reconstruction of the

Figure 11.5. A 6-month-old boy with history of pulmonary atresia and small right pulmonary artery (RPA). A 1.25 mm axial image obtained during controlled ventilation with deep conscious sedation on an eight-slice MDCT following 15 mL contrast by hand injection at 120 kVp and 40 mAs (effective dose estimate of 150 mrem).

CT data so as to be able to perform functional analyses such as ventricular wall motion and ventricular volume and ejection fraction calculations, typically the domain of MRI. Few studies have compared MRI and CT in functional assessment. One such study found no difference between MRI and CT in assessing right ventricle function in adults with tetralogy of Fallot (28,29).

Figure 11.6. A 3-month-old boy with hypoplastic right heart syndrome and small right pulmonary artery (RPA). A 1.25 mm axial image obtained during controlled ventilation with deep conscious sedation on an eight-slice MDCT following 10 mL contrast by hand injection at 80 kVp and 20 mAs (effective dose estimate 28 mrem). The radiation dose was decreased 80% compared with example shown in Figure 11.5 without loss of diagnostic quality.

Figure 11.7. Three-dimensional volume-rendered image of the coronaries in a 3-month-old boy with heart rate of 111 acquired in 3 seconds using ECG gating without sedation on a 64-slice MDCT scanner (GE Volume CT). Ao, aorta. (Images courtesy of Dr. Hauschild, San Diego Children's Hospital.)

In retrospective gating, the tube current is on during the whole cardiac cycle, for approximately five heart beats using a 64-MDCT system, so that data can be reconstructed during the most motion-free phases. This boosts the radiation dose three to four times compared to a nongated exam. The dose can be lessened by approximately 25% by using tube current modulation that reduces the beam strength during nonoptimal phases, near end-diastole and end-systole (20). There are limitations in successfully retrospective gating if the heart rate is too fast, which depends on the particular scanner used, with an upper limit of approximately 110 beats per minute on a 64-slice scanner (Fig. 11.7).

In prospective ECG gating, there is no dose penalty, but one cannot perform functional analysis, and the heart rates permissible are limited to <65 to 80 beats per minute. The x-ray beam is on only during a predetermined phase of the cardiac cycle with significant radiation dose savings (77 to 87%) (30,31). In adults, prospective gating resulted in images of similar quality to retrospectively gated coronary artery exams (30). The improved temporal resolution of dual-source scanners of <100 ms allows prospective gating in the systolic phase to image coronary arteries in babies who have high heart rates. Dual-source prospective gating mode may allow the entire thorax of a baby to be scanned in 1.3 seconds at a low radiation exposure of 0.5 mSv (32).

CT Scanners

Electron beam CT scanners are rarely used in CHD evaluation due to their poorer spatial resolution (3 mm). MDCT scanners are the current mainstay for cardiac imaging. Sixty-four channel scanners have the necessary spatial and temporal resolution for coronary imaging. The use of two simultaneous x-ray sources (dual source) coupled with two corresponding detectors allows a temporal resolution of <100 μ s because each of two arrays travels only 90 degrees to acquire sufficient data. The latest generation MDCT scanners utilizing 128 to

320 detectors have the potential to image the heart of an adult-sized patient almost instantaneously but the gantry is too wide to be of practical use for a small infant's heart.

Postprocessing CT Data Set

MDCT acquires a large volumetric isotropic data set of high spatial resolution, submillimeter in all three planes. Thus, MDCT excels at 3-D modeling. Interactively reviewing this data set at an independent workstation adds considerable diagnostic value, particularly in the setting of complex CHD in small children. The important relationships gleaned from this analysis can be saved as multiplanar two-dimensional (2-D) or 3-D reconstructions, which are ideal for discussions in case conferences and in therapeutic planning. A combination of 2-D multiplanar and 3-D maximum-intensity projection and volume-rendered images is most commonly used in the evaluation of CHD (4). A clear understanding of how the various reconstruction algorithms work and their pitfalls is necessary in order to avoid misrepresentation of the data due to partial volume averaging or artifacts (33).

INDICATIONS FOR CARDIAC CT

Problems in defining intracardiac morphology by echocardiography are usually handled with MRI even in infants because of the added functional information provided. The most common indications for CT are to evaluate the extracardiac vasculature in newborns and infants.

Pulmonary Arteries

The creation and maintenance of good pulmonary blood flow is a central theme in the management of CHD and is the goal of several common surgical procedures used to treat CHD: modified Blalock-Thomas-Taussig shunt, Glenn shunt, and Fontan procedure. Problems with the pulmonary arteries often occur postoperatively, such as with the arterial switch procedure, or are prevalent in certain conditions, such as tetralogy of Fallot. In children with pulmonary atresia/severe tetralogy, CT is helpful in identifying the source of pulmonary blood flow by determining the confluence and location of the mediastinal pulmonary arteries (5,34,35), the presence and size of a patent ductus arteriosus, and the presence and location of major aortopulmonary collaterals (MAPCAs) (36) and to identify pulmonary artery stenosis prior to surgery or as a postsurgical complication (Figs. 11.8–11.10).

Systemic and Pulmonary Veins

Left superior vena cava is more common in patients with CHD (37,38). In children with total or partial anomalous pulmonary venous return, CT is helpful in delineating the course and connections of the pulmonary veins and site of insertion of the draining vein and can identify postoperative vein obstruction (39–42). Total anomalous pulmonary venous return (TAPVR) is associated with heterotaxy syndrome (Figs. 11.11 and 11.12).

Aorta and Vascular Rings

Aortic coarctation may be difficult to differentiate from hypoplasia or interrupted aortic arch by echocardiography, particularly in the setting of a large patent ductus arteriosus. Echocardiography may also have difficulty

Figure 11.8. A 2-year-old boy with history of tetralogy of Fallot status after complete repair. Digital angiography spot film following injection of the right ventricle shows bilateral pulmonary artery stenoses (*white arrow*, right pulmonary artery; *black arrow*, left pulmonary artery).

MPA, main pulmonary artery; RPA, right pulmonary artery; LPA, left pulmonary artery; PV, pulmonary vein; LA, left atrium; AAo, ascending aorta; SVC, superior vena cava; IVC, inferior vena cava.

assessing the branching pattern of the great vessels in these disorders. Some vascular rings may have subtle findings (Fig. 11.13). There may be critical aortic aneurysmal dilatation in infantile Marfan syndrome, critical aortic stenosis (supra valvular and diffuse) in Williams syndrome, or small pseudoaneurysms as a complication of surgical or intravascular treatment.

Airway Abnormalities

Airway stenosis or malacia may occur secondary to prolonged intubation or to a vascular ring (Fig. 11.14) or extrinsic compression by dilated pulmonary arteries or therapeutic stents. CT may also identify a tracheal bronchus (43) or a bridging bronchus (44), which are associated with CHD (Fig. 11.15). A bridging bronchus is a lobar or segmental bronchus that arises from the contralateral bronchus.

Coronary Arteries

In infants and children, there is often no need for a comprehensive evaluation of coronary artery anatomy as in adults with atherosclerotic disease with the exception of aneurysms as a complication of Kawasaki disease (Fig. 11.16). Rather, it is important to delineate the origin and course of the proximal coronary arteries to identify anomalies that may interfere with a safe surgical correction or that may result in sudden death as in a young athlete. Potential anomalies of significance include anomalous origin from the contralateral aortic sinus (Fig. 11.17), single coronary artery, interarterial course of a coronary artery, pulmonary artery origin, high takeoff, and multiple ostia of the coronary arteries (45,46).

Figure 11.13. A 2-year-old with situs inversus and dextrocardia had acute respiratory distress and suspected vascular ring. Left side (A) shows a volume rendering of the vascular anatomy depicting a double aortic arch with a dominant left-sided and a hypoplastic right-sided arch. The ring encloses the trachea marked by an asterisk. B: Virtual tracheobronchoscopic views and fly-through of the trachea upon rerendering the same CT dataset. The arrows show the place and direction of the tracheal impression due to the pulsations of the ring. The pink arrows mark the position of the corresponding view. AAo and DAo, ascending and descending aorta, SVC, superior vena cava; MPA, main pulmonary artery.

Figure 11.14. A 3.5-month-old boy with pulmonary artery sling. Multiple volume-rendered images show compression of trachea (*green*) by the anomalous course of the left pulmonary artery (LPA). Note virtual bronchograms of lungs (*turquoise*) highlighting the capability of CT to simultaneously assess both heart and lungs. Left in anteroposterior and right in a left lateral view. MPA, main pulmonary artery; LPA, left pulmonary artery and RPA, AAO and DAAO, ascending and descending aorta.

The ability to visualize the proximal coronary arteries is inconsistent on nongated MDCT but better the older the child especially if they are capable of a breath hold (45,47). Gated MRI exams, particularly with good navigator sequences, are often successful in this regard in older children. In neonates, infants, and young children, gated CT exams are necessary to reliably assess the proximal coronary arteries (48). This requires fast temporal

resolution such as a 64 or greater MDCT or dual-source scanner (49). Breath holding may not be necessary in neonates (48).

There is an increased incidence of coronary artery anomalies in CHD. Presurgical identification is particularly important in patients with transposition of the great vessels, tetralogy of Fallot, truncus arteriosus, and pulmonary atresia with intact ventricular septum (45).

Figure 11.15. A 1.5-year-old child with bridging bronchus. Virtual tracheobronchoscopic views. The *pink arrows* mark the position of the corresponding view into and down the tracheo-bronchial system. After the "first" bifurcation (or the origin of a so-called bronchus suis or pig bronchus [arrow]), stenosis and cartilaginous tracheal rings could be appreciated (funnel trachea). The bronchial tree is getting wider with the origin of the "bridging bronchus" (the "real" right main bronchus).

Figure 11.16. Three-dimensional volume-rendered image of the coronaries of a young adult patient 15 years after Kawasaki disease: giant aneurysm of the right coronary artery and fusiform aneurysm of the left coronary artery including its bifurcation. The small images show curved MPR (multiplanar reconstruction) of the both arteries. Calcifications could be appreciated as wide spots in the vessel wall.

Figure 11.17. A 12-year-old boy was assessed with a 256-slice MDCT in a 3-second scan with prospective ECG gating (heart rate of 75 beats per minute). CTA shows an unknown anomaly of the coronary arteries. Left side; in a curved MP reformatted image, the left circumflex artery (LCX) arises from the right coronary artery (RCA) and follows a retroaortic pathway. On the right side, volume-rendered image shows the origins of all the coronary arteries. RIVA, ramus interventricularis anterior. (Courtesy of Dr. G. Gitsioudis, Heidelberg.)

Stents

Transcatheter placement of endovascular metallic stents is a common nonoperative way to treat stenoses of the pulmonary and systemic arteries and veins in children with CHD (50). A frequent complication of stents is the development of in-stent luminal narrowing due to intimal hyperplasia, stent

fracture (Fig. 11.18), and stent-related vascular narrowing or aneurysms (51,52). Conventional digital angiography is the gold standard for identifying in-stent restenosis, but it is not practical for long-term follow-up due to the fact that it is invasive and results in radiation exposure. In contrast to sonography and MRI, MDCT is surprisingly free of artifacts from the metallic component of stents (Fig. 11.19). (52). CT has been shown to accurately identify in-stent restenosis, even in small coronary arteries (53–55), but it is limited in detecting very mild intimal proliferation due to volume averaging from the metallic struts (56–58).

The ability of MRI to evaluate stents is dependent on the magnetic susceptibility of the material used as well as on the geometry and orientation of the struts and on the orientation of the stent in the main magnetic field (58,59). Stent artifacts are due not only to the induced magnetic field inhomogeneity but also are caused by radiofrequency shielding. For example, an MR black-blood imaging sequence, which is resistant to field inhomogeneity, still results in poor images due to shielding. MR seems to be able to provide diagnostic information on stent patency in stents made out of nitinol and tantalum and when high flip angle magnetic resonance angiography sequences are used (60,61).

CONCLUSION

CT technology continues to evolve new hardware and software modifications that result in faster scan times to reduce the need for sedation and to image better the coronary arteries while at the same time significantly lowering the radiation dose. With current ALARA protocols and MDCT scanners, CT provides a 3-D submillimeter evaluation of the heart and great vessels in a matter of seconds with little motion artifacts, potentially without the need for general anesthesia, and with much less radiation exposure than commonly thought. This powerful diagnostic tool plays an important role in infants and young children and the most critically ill children with CHD as a supplement to ultrasound evaluation and thereby decreases the number of diagnostic cardiac catheterizations needed and the radiation dose and sedation times utilized in the interventional cardiac lab.

Figure 11.18. A 7-year-old girl with history of aortic coarctation postangioplasty and aortic stent placement (green). Multiple volume-rendered images from an eight-slice MDCT obtained during a voluntary breath hold of the aortic arch show inward collapse of lumen of stent (arrows) on coronal projection not seen on sagittal views or on digital angiogram (top middle). MPA, main pulmonary artery; RPA, right pulmonary artery; Ao, aorta.

Figure 11.19. A 4-year-old child with an LPA stent. **A:** Digital angiogram shows narrowing or a moderate in stent restenosis which is greatest at its mid-portion. **B:** CTA 2-D multiplanar reconstruction of stent. **C:** Three-dimensional volume rendering shows stent (blue dashes).

Nathaniel W. Taggart ■ Allison K. Cabalka

Cardiac catheterization has a long and illustrious history, beginning in 1929 when Werner Forssmann (1), a surgical resident and future urologist, performed the first cardiac catheterization from an arm vein—on himself. He was subsequently awarded the Nobel Prize for his discovery. In the 1950s, the catheterization laboratory was used to understand the physiology of congenital heart defects. By the 1960s to 1970s, advances in cardiac surgery required more detailed anatomic information, which was addressed using axial angiography (2,3). In the 1980s, 2-D echocardiography made it possible for many patients to be diagnosed and treated without cardiac catheterization. In the 1990s, transesophageal echocardiography, computerized tomography, and magnetic resonance imaging were used to produce detailed cardiac images, further decreasing the need for diagnostic cardiac catheterization. However, as more complex cardiac conditions are treated, more detailed physiologic data are necessary for the evaluation and treatment of children with congenital or acquired heart defects. This chapter discusses the acquisition of hemodynamic data and angiographic images. Interventional techniques are discussed separately in Chapter 13.

DIAGNOSTIC CARDIAC CATHETERIZATION AND ANGIOGRAPHY

Indications

A thorough diagnostic cardiac catheterization provides complete physiologic and anatomic data. With the appropriate team, the risk of cardiac catheterization is low—usually less than the risk associated with clinical decisions based on inadequate information. The three major indications for performing a diagnostic cardiac catheterization are as follows:

1. A complete anatomic diagnosis or necessary hemodynamic information cannot be obtained by noninvasive methods.
2. Clinical signs and symptoms are not consistent with a patient's diagnosis.
3. A patient's clinical course is not progressing as expected.

Indications for catheterization in specific lesions are covered subsequently in the relevant chapters pertaining to each lesion.

Techniques

Planning the Study

In order to acquire complete and accurate information from cardiac catheterization, the cardiologist must have a clear understanding of the specific question(s) to be answered. Necessary preparation before cardiac catheterization includes a

thorough review of the patient's complete history and physical examination, including all previous pertinent noninvasive studies, cardiac catheterizations, and reviewing operative notes from all prior surgeries. Additional laboratory studies should be obtained as indicated by the clinical findings including electrolytes in patients taking diuretics, blood urea nitrogen and creatinine if there is concern for renal insufficiency, and blood typing for any patient in whom the complication risk is significant or in whom intervention potentially may be needed. Patients referred for cardiac catheterization may be severely ill or have various comorbidities. Recognition of these coexisting conditions and appropriate anticipation of potential complications is vitally important. Precatheterization planning should incorporate discussion of the case with the anesthesiologist. Airway management and the use of conscious sedation versus general anesthesia should be discussed and planned in advance of the catheterization procedure.

If a patient is anemic, transfusion prior to cardiac catheterization can optimize the baseline hemodynamic condition. Cyanotic patients who have significantly elevated hemoglobin levels are at increased risk of stroke during cardiac catheterization, due to polycythemia. Partial exchange transfusion may be considered prior to catheterization, but currently is rarely performed.

Premedication, Sedation, and Anesthesia

Physicians and institutions vary in their approaches to premedication, sedation, and anesthesia. Management is influenced by the diversity of cardiac defects and the expertise of the cardiologist and anesthesiology team. The goals of premedication and sedation or anesthesia are to decrease anxiety, facilitate parental separation, ensure comfort, promote amnesia, and facilitate the safe and efficient performance of the procedure. At the same time, sedation and mechanical ventilation may affect intracardiac hemodynamic measurements and can influence the applicability of the data acquired during the catheterization. The level of sedation during the catheterization and the use of supplemental oxygen should be discussed explicitly with the anesthesiologist before the beginning of the procedure. It is now standard to assign a person other than the primary cath physician to be responsible for sedation and airway monitoring. In most cases, this should be a cardiac anesthesiologist, particularly for patients with complex congenital heart disease, elevated pulmonary vascular resistance, or depressed myocardial function.

Prior to the catheterization, in general, pediatric patients should not have solid food for 8 hours, but may have milk or infant formula up to 6 hours prior, breast milk up to 4 hours before, with clear liquids up to 2 hours before the procedure. Certain patients should have an intravenous (IV) line placed in (preferably in an upper extremity) before arriving in the cath lab; this facilitates administering IV fluid (to ensure hydration) and sedation, especially in cyanotic or polycythemic patients.

Premedications can be administered orally or intravenously. Some children are best treated with mask induction first, prior to IV placement. The periprocedure management should be individualized for each patient based upon his or her age, level of anxiety, and specific cardiac defect/physiology.

Local anesthesia is administered prior to starting percutaneous access. Lidocaine is the usual anesthetic, which is painful when initially injected. Premedication diminishes the discomfort to lidocaine infiltration, as does buffering the lidocaine with sodium bicarbonate, pretreatment with a topical anesthetic cream (lidocaine 2.5% and prilocaine 2.5%), use of a small needle (25 gauge) to infiltrate the skin prior to infiltrating deeper tissues, and a slow rate of lidocaine infiltration. The dose of lidocaine should not exceed 6 mg/kg, as an excessive dose or accidental IV administration can cause seizures. Care should also be taken to assure that lidocaine is not injected intravascularly.

Effective sedation and analgesia can be maintained during the procedure using various IV medications, including fentanyl, midazolam, ketamine, and propofol. Cardiac depressant agents (e.g., propofol) must be used cautiously or avoided in patients with depressed cardiac function. Vasodilator agents should typically be avoided in patients with tetralogy of Fallot or similar physiology due to severe pulmonary outflow obstruction where systemic vasodilation may produce increasing right-to-left shunt. Conversely, ketamine can increase the systemic vascular resistance and may be useful in certain clinical settings. When administering sedative medications, it is important to observe any changes in heart rate, blood pressure, and pulse oximetry and to have appropriate airway support immediately available. In the current era, the majority of congenital cardiac catheterization procedures in pediatric patients are performed with general anesthesia, so the involvement of a cardiac anesthesiologist is paramount to assure a safe procedure.

Vascular Access

Establishing reliable vascular access is a vital early step to conducting a safe and efficient cardiac catheterization. Particularly in young children and neonates, hurried attempts at vascular access can result in significant bleeding or vessel damage, which in turn makes access more difficult.

Vascular access is most commonly obtained in the femoral system, with the catheterization procedure described as antegrade from the venous system or retrograde from the arterial system. Right heart catheterization is performed in an antegrade fashion through the great veins. Left heart catheterization is often performed in a retrograde fashion, but can also be accomplished antegrade across an atrial septal defect, patent foramen ovale (PFO), or via transseptal puncture. The type and location of vascular access necessary to perform the study are dictated both by the patient's particular anatomy and the objectives of the catheterization. For example, patients with a bidirectional cavopulmonary superior vena cava (SVC) to pulmonary artery anastomosis require internal jugular (IJ) or subclavian vein access to enter the pulmonary arterial tree.

Patients with congenital heart disease who have undergone multiple prior catheterizations and surgical operations may have obstruction of the systemic veins or femoral arteries, complicating vascular access. Previous catheterization reports can provide insight into difficulty with vascular access and whether complete vessel occlusion has been documented. Certainly, it is helpful to future operators if this is documented in the medical record, if not also with a digital record of the hand injection of contrast in the femoral venous system for confirmation. In such cases, alternative sites of vascular access should be explored. Occasionally, vascular ultrasound with color flow Doppler or other imaging modalities may be necessary prior to catheterization to identify available sites. The most common sites of venous access for cardiac catheterization are femoral,

IJ, and subclavian. Percutaneous arterial access is almost exclusively achieved via the femoral artery. Other modes of venous access include use of the umbilical vein or artery in the newborn or transhepatic route in patients who have multiple obstructed systemic veins.

Femoral Approach

Atraumatic percutaneous entry of the femoral vessels should be possible in nearly all pediatric patients. This requires knowledge of the anatomy, attention to detail, excellent technique, and patience. The most common approach, using a plain beveled needle with Seldinger technique, is described here (4).

The patient is positioned on the catheterization table with the hips elevated slightly, and the legs restrained in a straight or slightly inward rotation. Conversely, some physicians prefer to have the legs rotated outward in a more "frog-legged" position; this displaces the femoral vessels to a more lateral position. The anatomic landmarks are identified both before and after draping the patient. Consistent landmarks for determining the site of vessel entry are the anterior superior iliac spine, the symphysis pubis, the inguinal ligament, and the femoral pulse. In small patients, the inguinal ligament is palpable. The femoral vessels should be entered 1 to 2 cm below the inguinal ligament to ensure reliable hemostasis at the completion of the procedure. Vessel entry above the inguinal ligament is likely to result in a labial or scrotal hematoma or the more significant complication of retroperitoneal bleeding.

After the skin has been cleansed and a sterile field established, bony and soft tissue landmarks are again palpated to locate the femoral neurovascular bundle. This bundle courses vertically in the upper thigh and passes below the inguinal ligament approximately midway between the symphysis pubis and the anterior superior iliac spine. The femoral artery lies lateral to the vein and medial to the femoral nerve. Palpating the femoral pulse provides a reliable landmark for infiltration of anesthetic and, ultimately, needle puncture of the vein or artery. Ideally, the right femoral vein is accessed, as it provides a straight course to the right atrium (except in patients with situs inversus). Ultrasound with color flow Doppler can help determine vessel patency prior to attempted needle puncture. In the event that vessel patency cannot be documented by ultrasound, attention should be turned to the left-sided femoral vessels, which should also be evaluated by ultrasound. Due to the risk of complications, the use of ultrasound guidance for femoral access is becoming more commonplace (5) except in very young infants in whom the ultrasound probe may compress the vessels.

Once the vessel and surrounding landmarks have been identified, the overlying skin is infiltrated with a small amount of lidocaine, administered gradually to minimize the pain associated with administration. Too large a volume of lidocaine, particularly in small children, can distort the underlying vessels and make access more difficult. Once the skin is appropriately numbed, a hollow-bore needle, preferably with a short bevel, is introduced at a 30- to 45-degree to the skin, 1 to 2 cm below the inguinal ligament. The needle should be inserted using an "advance and wait" technique, observing for backflow of blood between 1- and 2-mm advances. If no backflow of blood occurs, once the needle is advanced to the bone, it should be withdrawn slowly and blood return monitored. It is also possible to advance the needle slowly with application of gentle aspiration using a syringe at this point if one is not used initially. Once consistent blood return is obtained, the needle is stabilized, and the soft end of the guide wire is advanced through the needle into the vessel lumen. The wire should advance freely; any resistance should be investigated. When accessing the femoral vein, the wire position can be confirmed with brief fluoroscopic imaging,

typically advancing the wire into the distal IVC. When accessing the femoral artery, it should be advanced to the lower abdominal aorta. Once the wire position has been confirmed, the needle is removed and an appropriate-sized hemostatic sheath is placed over the wire and advanced until the sheath hub is at the skin. The sheath is cleared of air by drawing back on a syringe attached to the sheath. Prompt blood return again confirms the position of the sheath within the vessel space, and connection to the monitoring pressure transducer confirms venous or arterial pressure.

When advancing the introducer wire through the needle, if the wire meets resistance immediately upon leaving the needle tip, it is most likely in the extravascular space and should be removed. If there is resistance to removing the wire, then the entire system should be removed to be sure that the wire is not sheared off beyond the end of the needle bevel. However, if the wire extends well beyond the tip of the needle before meeting resistance, the vessel may be obstructed. Obstruction can be confirmed by a small injection of contrast through the needle, using a slip-tip syringe, and imaged under fluoroscopy. This image of the obstructed vessel should be recorded and documented in the catheterization report for future reference.

Internal Jugular Approach

The IJ vein is the most common approach used when femoral veins are obstructed. It is the preferred approach for right ventricular endomyocardial biopsies (except in very young patients). The IJ vein is entered outside the thorax, so there is a low risk of pneumothorax. For appropriate positioning, the patient's head must remain turned to one side; thus in a sedated patient (particularly an infant), the airway may be compromised. Therefore, general anesthesia with endotracheal intubation is commonly used for IJ access. The right IJ vein is preferred (to the left) because it offers a more direct course into the right atrium, and the apex of the lung is lower on the right side. The patient is positioned with a soft towel roll under the neck to slightly hyperextend it with the head turned to the left. Landmarks to be identified before and after draping the patient are the carotid pulse and the two divisions of the sternocleidomastoid muscle. The right IJ vein lies below the sternocleidomastoid muscle, anterior and lateral to the carotid artery. Ultrasound guidance is mandatory for IJ access, and the IJ vein is visualized just lateral to the carotid artery. This spatial relationship is not universal, however. A growing body of evidence mandates that ultrasound guidance be used during puncture of the IJ vein to improve access success and decrease vascular complications (6–9). The IJ vein is distinguished from the carotid artery as gentle pressure with the transducer compresses the vein, and the artery has obvious pulsations with the heart rate. The skin is infiltrated with a small amount of lidocaine. With simultaneous ultrasound guidance, the access needle is advanced with constant gentle aspiration on the syringe until a free flow of blood return is obtained. Using fluoroscopic guidance, a guide wire is passed through the needle, into the vein, and is then advanced into the right atrium (or pulmonary artery in a cavopulmonary anastomosis).

Subclavian Approach

The subclavian vein is posterior to the clavicle, superficial and inferior to the subclavian artery, lying partly on the pleura. As a result, complications of subclavian vein access include pneumothorax, hemothorax, and intravascular air. Complications are more likely to occur when there is pulmonary parenchymal disease, pulmonary hypertension, or anatomic thoracic abnormalities (including previous surgery).

The patient is positioned with a small roll under the shoulders. Airway adequacy is verified before proceeding. Prior to draping the patient and again before vessel entry, one should

identify important landmarks, specifically the suprasternal notch and the depression at the lateral third of the clavicle. With the usual anatomy of a right SVC and left innominate vein, left subclavian vein access is preferred. In the region of clavicular depression, the skin, subcutaneous tissues, and clavicular periosteum are infiltrated with lidocaine. The needle, with attached syringe, is advanced gently through the skin until it contacts the clavicle, then it is “walked” under the clavicle. The needle must be oriented anteriorly to avoid entering the subclavian artery or the apex of the lung. Once under the clavicle, the needle is advanced slowly with constant gentle aspiration until a steady venous blood return is obtained. Using fluoroscopic guidance, the soft end of a wire is advanced through the vein into the right atrium (or the pulmonary artery in a cavopulmonary anastomosis). Due to negative intrathoracic pressure, air will be sucked into the vein if the needle is left open to air or if there is a mismatch between the size of the needle lumen and the wire diameter, especially if the patient is breathing spontaneously. Because of the risk of intravascular air, a sheath with a bleedback valve is always used.

Umbilical Approach

Umbilical venous access is generally possible until the third day of life. The umbilical artery may be cannulated up to 1 week of age. It is best to avoid maneuvering a wire directly through the umbilical vessels. Often, infants arrive in the cath lab with umbilical lines in place. An indwelling umbilical vein catheter with its tip in the right atrium can be exchanged over a 0.018- to 0.021-in guide wire for a sheath and dilator; the sheath should be long enough to cross the ductus venosus and just enter the right atrium, but not so long as to puncture the right atrium. An indwelling umbilical arterial line may be exchanged over a wire; however, the circuitous course of this vessel makes catheter exchanges difficult. The use of a sheath in the umbilical artery is optional.

Catheter manipulation is difficult from the umbilical vessels. An umbilical venous catheter is directed toward the roof of the left atrium, across the PFO. Directing it to any other location will usually require the use of a deflecting wire. With an umbilical arterial catheter, the initial inferior loop that the umbilical artery takes before joining the internal iliac artery limits the ability to manipulate the catheter. It is important to use very gentle technique during cardiac catheterization in the newborn heart, as the cardiac walls are very thin—especially in the atria and left ventricular apex—and the chambers are small. Since small sheaths and catheters (3 and 4 Fr) can be placed in the femoral vessels, the benefits of improved catheter manipulation make a femoral approach preferable in most cases, even when the umbilical vessels are available.

Hepatic Approach

In the mid to late 1990s, transhepatic venous access was first described as an alternative to traditional venous access sites in limited clinical situations (10,11). When femoral, jugular, or subclavian venous access to the right atrium is not possible, a hemostatic sheath can be placed within a hepatic vein. This is particularly useful for device closure of an atrial septal defect when the IVC is interrupted or thrombosed. Overall, however, transhepatic venous access is infrequently used.

After the appropriate sterile preparation and local anesthesia (including infiltration of into the hepatic parenchyma), the skin is punctured along the mid to anterior axillary line at the subcostal margin using a long 21 or 22 gauge needle with or without an obturator. The needle is directed posteriorly, superiorly, and medially, toward the left shoulder. Historically, the needle is advanced under fluoroscopic guidance, but some have advocated for ultrasound guided access (12). When the tip of the needle is approximately 1 cm from midline, the obturator

is removed. Blood return with or without gentle aspiration suggests that the needle is in the vascular space. Positioning is then confirmed with a contrast injection; if contrast flows to the heart, the needle is in an appropriate hepatic vein, whereas if contrast flows into the liver parenchyma, the needle is in a portal vein and should be repositioned. Once the needle is found to be within an adequately sized hepatic vein, a 0.018-in wire is passed through the needle into the right atrium or SVC. With the needle removed, a stiff introducer is advanced over the wire, which is then exchanged for a larger 0.035- or 0.038-in wire. The introducer is then exchanged for the necessary hemostatic sheath with the tip of the sheath positioned in the low right atrium.

Catheter manipulation through hepatic venous access may be more troublesome than traditional femoral venous access. Directing catheters into the right ventricle and pulmonary arteries frequently requires creative use of preshaped catheters and deflecting wires.

Hepatic venous access also carries the risk of some unique complications, including intraperitoneal bleeding, hemobilia, gall bladder perforation, portal vein thrombosis, and liver abscess or peritonitis. Closure of the hepatic tract following sheath removal may depend on the need for ongoing anticoagulation, size of sheath used, and hemodynamic status; often hemostasis may be obtained with pressure (13).

Catheters and Wires

Functioning competently in the congenital cardiac catheterization lab requires an understanding of the various equipment and tools available to the cardiologist. Specifically, the cardiologist needs a practical familiarity with the different catheters and wires available in the cath lab.

For the most part, catheters are hollow, allowing for transmission of pressure measurements, sampling of blood, and infusion of medications or contrast. In general, catheters can be classified as end-hole or side-hole. For the most part, end-hole catheters are used for hemodynamic measurements, blood gas sampling, and contrast injection into smaller vessels by hand. Angiographic injections are primarily performed using side-hole catheters. Catheters may be straight or shaped. Figure 12.1 illustrates some examples of different catheter shapes.

Right heart catheterization is typically performed using soft, balloon-tipped catheters. An end-hole balloon wedge catheter

is used for hemodynamic pressure measurement and blood gas sampling. When the balloon is inflated with a small volume of CO₂ and with small amount of manual torque, the catheter will follow the flow of venous blood into right atrium, across the tricuspid valve into the right ventricle and from the right ventricle into the pulmonary arteries. With the balloon-tipped end-hole catheter positioned in a distal branch pulmonary artery, gentle balloon inflation of the balloon allows for measurement of pulmonary artery wedge pressure. Angiography of the right heart is usually performed using a balloon-tipped angiographic catheter, which has side holes proximal to the balloon.

Left heart catheterization is typically performed using smaller caliber, thin-walled, but more rigid, catheter. A pigtail catheter is advanced to the descending aorta over a wire. With the wire removed, the catheter end is curled, allowing it to be advanced and withdrawn in the aorta without engaging smaller branch arteries. However, in order to advance the pigtail catheter into the left ventricle, a soft, typically tight-J-tipped wire is used to cross the aortic valve to prevent leaflet damage. Pressure measurements, blood sampling, and angiography can all be performed using the pigtail catheter.

Wires can be used to direct or stabilize catheters. Like catheters, wires come in many different diameters. Most wires have a soft distal end, which comes in various contours, including straight, J-tipped, and angled. Wires advanced through hollow catheters are used to probe and enter vessels that may be otherwise difficult to access with the catheter alone, such as stenotic branch pulmonary arteries or tortuous collateral vessels. Wires can also be used to cross a PFO for access to the left atrium and pulmonary veins. Stiff wires are used to stabilize catheters for angioplasty and valvuloplasty. Stiff, extra-long wires are valuable for maintaining position while exchanging one catheter for another.

Many other catheters and wires of various sizes, lengths, and contours are available for use depending upon the specific clinical scenario, but an expansive discussion is beyond the scope of this chapter.

Catheter Manipulation

A detailed discussion of catheter manipulation is beyond the scope of this chapter, but several points deserve mention. In the neonate and infant, cardiac tissue is thin. Perforation can occur easily, especially in the atrial appendages, right ventricular

Figure 12.1. A: Angiographic catheters, the NIH catheter (USCI, Billerica, MA), and the Berman angiographic catheter (arrow, Reading, PA) have side holes but no end hole. The NIH catheter is a relatively stiff catheter, and with the angled tip, it responds well to torque maneuvering. The Berman catheter is soft and balloon tipped; it can be flow directed but it is more difficult to effectively torque. B: Pigtail catheters (Medi-Tech, Watertown, MA; and UMI, Ballston Spa, NY). These are thin-walled catheters that have both end and side holes, designed to deliver a large volume of contrast quickly for ventriculography. They may be angled and may have radio-opaque markers to facilitate making measurements. Note the smaller diameter curve on the right catheter, which is better for neonates and infants. C: Balloon wedge pressure catheter (arrow). This is an end-hole, balloon-tipped catheter that is not used for angiographic purposes; however, it may be used for hand injections (with or without balloon-occlusion). D: End-hole catheters. There are many preformed end-hole catheters designed for selective entry of noncoronary vessels. The catheters may be used for selective angiography by hand injection. Pictured are Cobra and Berenstein (Medi-Tech) catheters. E,F: Coronary artery catheters. These catheters are designed for selective hand injection of normally originating right and left coronary arteries. Pictured are the Amplatz left and right (E) and the Judkins left and right (F) (Cook, Bloomington, IN) coronary catheters.

outflow tract, left ventricular apex, and aortic valve cusps. The risk of perforation can be decreased by gentle catheter manipulation, using small movements, the use of balloon catheters, and a thorough understanding of the cardiac anatomy and the desired catheter route and destination. The importance of reviewing *all* previous imaging studies *before* the catheterization cannot be overemphasized. If a catheter is too straight to manipulate to the desired location (e.g., across the tricuspid valve), it may be safely curved outside the body, in a hepatic vein, or using a tip-deflecting or shaped wire, rather than within the heart. The small catheters used in infants and children can be damaged by vigorous manipulation. Thin-walled catheters, such as pigtails, should be advanced over a wire. Large catheter loops in the atrium or right ventricular outflow tract can cause hemodynamic instability owing to reflex bradycardia or tricuspid valve insufficiency; therefore, one needs to pay attention to all parts of the catheter, not just the tip.

Collection of Hemodynamic Data

The purpose of a diagnostic heart catheterization is to collect data that will be used to define the patient's condition and make management decisions. The calculations made using data obtained during catheterization assume that blood samples and pressure measurements were obtained at a steady physiologic state. Changes in oxygenation, ventilation, heart rate, and blood pressure will directly affect these calculations and may produce inaccurate data that, in turn, can result in suboptimal patient management. Because a true "steady state" is rarely encountered in the cath lab, it is important to recognize any changes in heart rate, blood pressure, and oxygen saturation and how these changes will affect the accuracy of the data. The patient's condition, oxygen saturation (or blood gas) samples, and hemodynamic data must be continually assessed for validity. The operator should be constantly aware of the patient's hemodynamic state, and inconsistencies in the data must be clarified before the catheters are removed. Initial interpretation of all data obtained should be performed before leaving the cath lab to be certain that the information deemed necessary has been obtained. Although separated for purposes of discussion, the collection of hemodynamic/pressure data and oxygen sampling occurs simultaneously during the initial phases of the catheterization procedure.

Diagnostic heart catheterization typically begins with assessment of the initial arterial blood pressure, venous filling pressures, and measurements of oxygen saturations in the SVC and femoral artery. These data provide immediate information about the patient's initial hemodynamic status, which is a crucial aspect of the procedure. One needs to assess initial blood pressure to be sure that the hemodynamic data recorded will be valid. Detection of shunts and quantifying resistance depends on the measurement of various flow indices, and for the purposes of this discussion, oxygen content (saturation) will be used as the primary indicator with respect to these calculations (see further discussion below). Children with an SVC saturation <60% or arterial saturation <70% have limited cardiac reserve. All factors influencing their conditions (i.e., body temperature, ventilatory status, acid-base balance, and volume status) should be assessed at the start of the procedure and maintained at an optimal steady state during the procedure. Since variation in any of these factors can affect the data obtained during catheterization, all procedures should be completed as expeditiously as possible.

Any abnormal data must be verified promptly in the cath lab. Abnormal pressure tracings should be compared to those expected or to baseline, and transducers recalibrated frequently to be sure they are properly zeroed. When sampling saturations, for instance, elevated pulmonary artery saturation should prompt the operator to identify whether the catheter was partially wedged or whether there is a left-to-right shunt. In addition, a significant "step-up" in saturation between

Difference in arterial-venous oxygen saturation

Figure 12.2. Graph displaying the relationship between cardiac index and varying arteriovenous oxygen saturations using an assumed oxygen consumption = 140 mL/min/m². Note the greater cardiac index with a hemoglobin of 12 g/dL (diamonds) compared with 16 g/dL (circles).

consecutive cardiac chambers suggests the presence of a left-to-right shunt.

After collecting all saturations and pressures, and before proceeding to angiography, it is important to assess the pulmonary and systemic flows, resistances, and flow ratios. Systemic flow index can be estimated by recognizing that an arterial-venous (A-V) oxygen (O₂) saturation difference of 20% to 25% corresponds to a "normal" cardiac index of approximately 3.5 L/min/m². A larger A-V O₂ difference correlates with a lower cardiac index. In addition, for a given A-V O₂ difference, the higher the hemoglobin level, the lower the flow index (Fig. 12.2). A simple formula to estimate pulmonary flow index (Q_p) compared to systemic flow index (Q_s) is the ratio of pulmonary A-V O₂ divided by systemic A-V O₂. Details of calculations for flow indices and resistance are discussed later in this chapter.

Measurement of Hemodynamic Variables

The primary goals of any detailed hemodynamic catheterization are to measure pressures in all of the pertinent cardiac structures/chambers and to obtain oxygen samples in these structures, in order to calculate systemic and pulmonary flow indices and vascular resistance.

Pressure Measurements

In the cath lab, pressures are most often measured using fluid-filled catheters connected to pressure-sensitive transducers. The change in pressure (force/unit area) in the cardiac chamber or vessel is transmitted along a column of incompressible fluid (saline or blood) contained within a nonexpansile tube (catheter) to a transducer. The transducer contains a diaphragm that moves a small distance (in a linear fashion) in response to change in pressure. The movement of the diaphragm is transmitted to an electronic strain gauge. The strain gauge converts pressure changes into voltage changes. These voltage changes are then converted into an electric signal, which is displayed as a waveform over time on a computer monitor. Systolic and diastolic pressures are measured instantaneously as the peak and trough, respectively, of the waveform. A mean pressure is obtained by electronic damping of the signal over several cardiac cycles. The system is calibrated to a zero point at level of the center of the heart. It is

important to understand potential sources of error and artifact in the pressure tracings obtained. Two important concepts are frequency response (the ratio of output amplitude to input amplitude over the range of frequencies of the input pressure wave) and damping (the dissipation of the energy of oscillation of a pressure measurement system). Inaccurate pressure waveforms frequently are related to deterioration of the frequency response or to overdamping or underdamping. Other references contain a more complete discussion of these principles (14). Eight potential sources of pressure tracing artifact and recommendations for identifying the source of artifact and error are listed below:

1. Loose connections in the system: These usually result in an overdamped tracing. Backup of blood into the transducer tubing is an indication of a loose connection.
2. Air in the system: This is probably the most common cause of measurement error. Air may be introduced into the system at any of the connections, or dissolved air may come out of the saline used to flush the system. Air is compressible and its presence in the system lowers the frequency response. As a result, information inherent in the applied pressure wave is lost, producing what is commonly referred to as a damped tracing. Another indication of air in the system is the amplification of high-frequency input, producing overshoot or "fling" in the tracing. The appearance of a small amount of blood with obvious pulsatility in the transducer tubing is an indication that there is air in the system.
3. Inaccurate calibration or baseline drift: Even if the transducers are properly calibrated or "zeroed" at the beginning of the procedure, movement of either the patient or the transducers, or electric drift of the baseline, may result in inaccurate pressure recordings. Although small errors in calibration may be inconsequential in arterial recordings, they can have a significant impact in the measurement of venous pressures and pulmonary vascular resistance.
4. Partial catheter obstruction: This is usually the result of the catheter clotting or kinking. This usually occurs when small or thin-walled catheters are used. If blood is allowed to remain in the catheter lumen for any length of time, deposition of fibrin or platelets will reduce the lumen size, decreasing the frequency response.
5. Catheter "fling": The appearance of fling (a tall, narrow spike) on a pressure recording has many causes. Overshoot, produced by air in the system, has been discussed. Rapid movement of the catheter tip, which may occur if the tip lies in a turbulent jet, can result in superimposition of high-frequency oscillations on the pressure recording. If the catheter is contacted by a cardiac structure (such as the mitral valve), the superimposed oscillation can alter the waveform dramatically. At times, these conditions are unavoidable. To minimize this error, use the mean systolic pressure rather than the peak systolic pressure, or inject a small amount of blood or contrast media in the tubing to intentionally damp the system.
6. End-hole artifact: When a column of blood stops suddenly against an end-hole catheter, kinetic energy is transformed into pressure energy, and the recorded pressure is falsely elevated. Similarly, when a column of blood is moving away from an end-hole catheter, the pressure recorded will be less than the true intravascular pressure, in proportion to the velocity of flow. This explains why the pressure in a stenotic proximal pulmonary artery has a lower peak systolic pressure than the distal larger vessel.
7. Peripheral pulse wave amplification: Both the peak systolic pressure and the pulse pressure are amplified with increasing distance from the aortic valve. The mean pressure, however, remains the same. This phenomenon is demonstrated by recording the pressure tracing during a pullback around the aortic arch, where the systolic pressure increases from the ascending to the descending aorta. While peripheral

pulse wave amplification is a physiologic phenomenon and not an artifact, per se, it may lead one to incorrectly interpret pressure data. When comparing the ascending aorta systolic pressure with the femoral or radial artery systolic pressure, failure to take into account pulse wave amplification will result in underestimation of a pressure gradient across an aortic valve or coarctation of the aorta.

8. Catheter entrapment: An end-hole catheter placed in a small or heavily trabeculated ventricle can trap a small volume of fluid, resulting in an exaggerated pressure elevation during systole. This error can be eliminated by slightly withdrawing the catheter or deflating the balloon (if a balloon-tipped catheter is used). If these maneuvers are not possible, the pressure should be recorded using a side-hole catheter, provided that all of the side holes are within the chamber or vessel of interest.

Transducer-tipped wire catheters, such as the Radi wire, allow direct pressure measurement without relying on the propagation of fluid waves through a fluid-filled catheter (15). Such wire catheters consist of a floppy wire end distal to the transducer, which prevents the manometer from being damaged or puncturing the vessel or chamber wall. The pressure wire is connected to an analyzer system that displays numeric pressures and waveforms on a monitor. The pressure wire is introduced through an end-hole catheter. When the manometer reaches the end of the catheter, the wire and catheter pressures are calibrated on the monitoring system. The pressure wire is then advanced from the catheter into the vessel or chamber in question. Pressure wire manometry allows simultaneous pressure measurements in two contiguous locations, such as simultaneous ascending and descending aorta pressures in a patient with coarctation of the aorta. This technique may also be used to carefully record the pressure differential across a mechanical valve, with very gentle manipulation of the wire across the prosthetic valve opening. In the case of an aortic prosthesis, the retrograde catheter remains in the ascending aorta, whereas the pressure wire is advanced retrograde across the valve into the left ventricle. The thin pressure wire is also useful for obtaining pressure measurements distal to narrow communications that may be difficult to access with a catheter alone, such as the pulmonary artery pressure in child whose sole source of pulmonary blood flow is via a modified Blalock-Thomas-Taussig shunt (16).

Right Heart Catheterization

Characteristic right heart waveforms are shown in Figure 12.3 and normal hemodynamic pressure values for children are shown in Table 12.1. There are three characteristic waves in the right atrial tracing; a, c, and v waves. The a wave represents atrial systole and occurs just after the P wave on the electrocardiogram. The c wave is due to either right ventricular contraction or tricuspid valve closure, whereas the v wave results from filling of the right atrium against a closed tricuspid valve. The decrease in pressure after the a wave is the x descent, which is due to atrial relaxation. The decrease in pressure after the v wave is the y descent, which represents the opening of the tricuspid valve in early diastole.

Normally, the right atrial a wave exceeds the v wave by 2 to 3 mm Hg, neither wave exceeds 8 mm Hg, and both waves are within 5 mm Hg of the mean right atrial pressure. An elevated a wave is seen in the context of restricted right ventricular filling, such as tricuspid stenosis or a noncompliant right ventricle (e.g., pulmonic stenosis, pulmonary atresia, or pulmonary hypertension). So-called cannon a waves may be seen with certain arrhythmias, when atrial contraction occurs after right ventricular contraction has closed the tricuspid valve. Elevated v waves are seen with tricuspid regurgitation,

Figure 12.3. Right heart pressures (each horizontal line = 2 mm Hg). A: Right atrium: a wave = 3, c wave = 1, v wave = 2. B: Right ventricle: 20/0.2. C: Pulmonary artery: 20/10. D: Pulmonary capillary wedge: a wave = 14, v wave = 16.

Ebstein anomaly, or a left ventricular-to-right atrial shunt. The right atrium and venae cavae are compliant structures that can accept a large volume of blood with minimal change in pressure; thus, the v wave may not necessarily be elevated in the aforementioned conditions. Elevation of the mean pressure is seen with any condition that elevates the a wave or v wave, or in the context of myocardial failure. Low right atrial pressure (<1 to 2 mm Hg) suggests hypovolemia. Marked variability of the a wave and mean pressure may be seen with atri-

oventricular dissociation or with obstructive airway disease. A patient who is breathing spontaneously but has significant airway obstruction may have negative intrathoracic pressure and subatmospheric right atrial pressure, which may result in the introduction of air into the system if the catheter is not properly connected or the hub is maintained below the level of the chamber.

The right ventricular pressure tracing has a rapid upstroke during isovolumic contraction, a plateau during systolic ejection, a decline to near zero during isovolumic relaxation, and a slow rise to the end-diastolic pressure during diastolic filling. Normally, the peak systolic pressure is <30 mm Hg, and the end-diastolic pressure is <8 mm Hg. Except in the context of tricuspid valve stenosis, the end-diastolic pressure corresponds to (and should be equal to) the right atrial a wave. Right ventricular systolic pressure is elevated in the presence of a large ventricular septal defect, right ventricular outflow tract obstruction, and pulmonary hypertension. Recordings should be obtained in the apex and in the outflow tract to confirm the absence of any intracavitary gradient.

The normal pulmonary artery systolic pressure is equal to the right ventricular systolic pressure (<30 mm Hg), and the mean pressure is <20 mm Hg. Pulmonary artery diastolic pressure begins with the dicrotic notch caused by valve closure, and the end-diastolic pressure is typically 2 to 3 mm Hg higher than the wedge pressure. Increased pulmonary artery pressure occurs with distal obstruction to flow, such as with peripheral pulmonary stenosis, pulmonary arteriolar obstruction, pul-

TABLE 12.1

Normal Hemodynamic Pressure Measurements in Children

Chamber/Vessel	Systolic	Diastolic	Mean
Right atrium			3 ± 1
Right ventricle	25 ± 5	4 ± 2	
Pulmonary artery	22 ± 4	10 ± 3	13 ± 3
PA wedge			8 ± 2
Left ventricle	110 ± 12	9 ± 2	

Values are compiled from data published in references. All pressures are in mm Hg. PA, pulmonary artery.

monary thromboembolism, pulmonary venous obstruction, or left atrial hypertension (due to other causes such as cor triatriatum, mitral stenosis, or left ventricular diastolic dysfunction). Pulmonary artery pressure is also elevated in the presence of aorta-pulmonary artery communications (such as patent ductus arteriosus or aortopulmonary window) or a significant ventricular septal defect (if there is no pulmonic stenosis). In the presence of pulmonary hypertension, a pulse pressure of <40% of the peak systolic pressure suggests a fixed resistance, whereas a wide pulse pressure (>60% of the peak systolic pressure) suggests high flow and low resistance.

Systolic pressure gradients between right ventricle and pulmonary artery are due to right ventricular outflow tract obstruction, although gradients of 5 mm Hg may be normal. Gradients ≤ 10 mm Hg may be seen with structurally normal pulmonary valves and increased blood flow, as with a large atrial septal defect. In the setting of very severe branch stenosis or a very tight pulmonary artery band, the catheter may produce enough obstruction of the vessel as it crosses the stenosis that the pressure distally resembles the wedge pressure tracing.

Pulmonary artery wedge pressure is usually a good reflection of the left atrial and left ventricular end-diastolic pressures because of the absence of valves in the pulmonary circulation. When an end-hole catheter is appropriately wedged in a pulmonary artery branch, the distal pulmonary venous pressure is transmitted retrograde through the capillary bed and arterioles to the catheter tip. When using a balloon-tipped wedge catheter (end-hole), the catheter is advanced as far as it can into the distal pulmonary artery and the balloon is partially inflated while monitoring the tracing for its characteristic appearance. The wedge tracing should have the characteristic a and v wave appearance of an atrial tracing (Fig. 12.3). The wedged catheter position is confirmed by observation of the characteristic left atrial waveform or by withdrawal of fully saturated blood. When small catheters are used, it may not be possible to withdraw a blood sample from the wedged position. Interpretation of the wedge pressure must be guided by an understanding of the anatomy. The pulmonary artery wedge pressure does not reflect the left ventricular end-diastolic pressure when there is pulmonary vein stenosis, cor triatriatum, mitral stenosis, or anomalous pulmonary venous return. When the wedge pressure is elevated, these lesions must be confirmed or ruled out by direct measurement of the left atrial or left ventricular end-diastolic pressure.

Left Heart Catheterization

Characteristic left heart waveforms are shown in Figure 12.4 and normal pressure values for are shown in Table 12.1. The

normal left atrial mean pressure is 6 to 10 mm Hg (depending on age), which is several mm Hg higher than the right atrial mean pressure. In contrast to the right atrium, the left atrial v wave is usually higher than the a wave, and neither is >5 mm Hg above the mean pressure. An elevated a wave is seen with defects resulting in left atrial outflow obstruction (mitral stenosis, supravalle mitral membrane) or with diseases that impair left ventricular compliance (aortic stenosis, coarctation of the aorta). The a wave may be dominant with an atrial septal defect, as a large atrial septal defect allows transmission of pressure across the septum, or with diseases that elevate the right atrial a wave. Elevated v waves typically occur with mitral regurgitation. Elevation of the left atrial mean pressure (and both the a and v waves) may be encountered with large left-to-right shunts at the ventricular or great vessel level or as a sign of left ventricular failure. If the end-diastolic pressures in the left atrium and left ventricle are not equal, some form of mitral valve obstruction is present. Higher gradients (>8 to 10 mm Hg) suggest structural mitral stenosis, whereas lower gradients suggest physiologic stenosis due to increased blood flow across the valve, such as from a large ventricular septal defect. When transseptal technique is used to enter the left atrium, one can use a smaller diameter catheter to advance into the left ventricle and simultaneously measure left atrial and left ventricular pressure.

The peak systolic pressure in the left ventricle should be equal to or up to 5 mm Hg greater than the peak systolic pressure in the ascending aorta. A gradient between the left ventricle and the aorta is present in dynamic left ventricular obstruction (as in hypertrophic cardiomyopathy), subaortic stenosis, or aortic valve stenosis. The normal aortic pressure is a reflection of left ventricular stroke volume and systemic vascular resistance. Near the aortic valve, the arterial waveform displays a relatively slow upstroke, a broad peak, and a near-linear drop to end-diastole. In the distal arteries, the peak becomes sharper, the dicrotic notch (representing the decrease in pressure with closure of the aortic valve) becomes more obvious, and pulse wave amplification occurs.

The pulse pressure in the ascending aorta is usually 25 to 50 mm Hg, or <50% of the peak systolic aortic pressure. Increased pulse pressure and low diastolic pressure may be seen with aortic insufficiency, a ruptured sinus of Valsalva, or conditions in which there is a low-resistance diastolic runoff such as patent ductus arteriosus, aortopulmonary collaterals, aortopulmonary window, truncus arteriosus, and systemic AV fistula. A narrow pulse pressure may be encountered in pericardial tamponade or low cardiac output states. A gradient between the ascending and descending aorta suggests coarctation of the aorta.

Figure 12.4. Left heart pressures. A: Left atrium (each horizontal line = 2 mm Hg): a wave = 13, v wave = 16. B: Left ventricle (each horizontal line = 10 mm Hg): 98/0.6. C: Aorta (each horizontal line = 10 mm Hg): 98/50.

Derived Hemodynamic Variables

Measurement of cardiac output, in terms of pulmonary and systemic blood flow, is a necessary first step to quantifying shunt volume and vascular resistance. Because cardiac output cannot be measured directly, it can be estimated using the indicator dilution technique described by Fick (17). The indicators most commonly used are oxygen or cold saline (thermodilution) (18). Various analogies have been used to explain the concept of the Fick principle. In one analogy, a coal-bearing train, representing blood, passes through a coal-loading station (capillary bed) at a constant but unknown rate (cardiac output). The train consists of a series of cars (hemoglobin), each of which have a known load of coal (oxygen content). By knowing the rate of delivery of the coal (oxygen uptake) and the amount of coal in the cars before and after the station, one can easily calculate the rate at which the train is moving through the station. In quantitative terms, cardiac output can be calculated as follows:

- Blood flows at an unknown rate.
- An indicator is present in the blood in a measurable concentration.
- The indicator is added or removed at a known rate.
- Measurement of the change in concentration of the indicator allows one to calculate flow as follows:

$$\text{Flow} = \frac{\text{Rate of addition or removal}}{\text{Change in concentration}}$$

Oxygen in the Blood

Oxygen is the most common indicator that is used for purposes of calculating flow and resistance in the congenital cardiac patient. Because the quantity of oxygen in the blood that is being sampled directly affects the calculation of cardiac flow rates, it is important to be able to accurately measure or estimate the oxygen content of a blood sample.

Oxygen is carried in the blood in two forms: either attached to hemoglobin or dissolved in plasma. The amount of oxygen bound to hemoglobin is influenced by many factors including the partial pressure of oxygen (pO_2). In addition, the affinity of hemoglobin for oxygen is inversely affected by hydrogen ion concentration, partial pressure of carbon dioxide, level of 2,3-diphosphoglycerate (DPG), and temperature. Affinity for oxygen is also affected by the type of hemoglobin. For example, hemoglobin F (fetal hemoglobin) has a higher affinity for oxygen than the more common hemoglobin A.

The term oxygen capacity refers to the amount of oxygen that can be bound by hemoglobin in blood; maximum oxygen capacity is 1.36 mL O_2 per 1 g of hemoglobin. Thus, oxygen capacity (mL O_2 /dL) can be calculated as

$$\text{Oxygen capacity (mL } O_2 / \text{dL)} = \text{Hemoglobin (g / dL)} \times (1.36 \text{ mL } O_2 / \text{g of hemoglobin})$$

The actual amount of oxygen bound to hemoglobin in a given sample of blood is calculated as the oxygen capacity multiplied by the oxygen saturation of hemoglobin. Oxygen saturations in the blood samples are measured spectrophotometrically. Oxidized hemoglobin and reduced hemoglobin have different spectral absorptions at 650 nm but similar ones at 805 nm. Oximeters measure the absorption at 650 nm to represent the amount of oxidized hemoglobin and the absorption at 805 nm to represent total hemoglobin; the ratio of these two numbers is the oxygen saturation. The method is most accurate at oxygen saturations between 60% and 95%, as long as there are no other substances in the blood that affect the spectral absorption (e.g., carboxyhemoglobin).

It is important to remember that oxygen saturation values report only the amount of oxygen that is *bound* to hemoglobin and does not account for *dissolved* O_2 . In room air, the vast majority of oxygen in the blood is bound to hemoglobin, whereas the amount of dissolved oxygen is very small, so dissolved O_2 is typically ignored in calculations made in room air at baseline. In contrast, if the patient is inhaling 100% oxygen, with pO_2 values that may reach 500 mm Hg, dissolved oxygen becomes very important relative to the amount bound to hemoglobin, and this must be accounted for in the calculations.

Dissolved oxygen in plasma is determined by the solubility coefficient of oxygen, temperature, and the pO_2 . At 37°C (body temperature), the amount of oxygen dissolved in blood is 0.003 mL/mm Hg/dL. As mentioned, the amount of oxygen dissolved in plasma is usually not significant enough to include in the calculations for the patient breathing room air, but accounting for dissolved oxygen becomes very important when the patient is breathing 100% oxygen or has low hemoglobin. To put this in perspective, in arterial blood with a pO_2 of 100 mm Hg (typical for an oxygen saturation of 100% in room air), there is only 3 mL of dissolved oxygen *per liter*. This amount of oxygen is small relative to the amount of oxygen bound to hemoglobin. However, if the patient is receiving supplemental oxygen, with the $pO_2 > 100$ mm Hg, dissolved oxygen contributes more significantly to the total oxygen content and must be considered in hemodynamic calculations. In this situation, for example, if the arterial pO_2 is 500, there will be 15 mL of dissolved oxygen per liter, a much greater percentage that must be accounted for in assuring accurate calculations. Dissolved oxygen should also be considered in the setting of low hemoglobin, as the carrying capacity of the blood is lower; therefore, the relative percentage accounted for by dissolved oxygen is higher.

The *total* oxygen content in a sample of blood is the sum of dissolved oxygen in the blood and the oxygen that is bound to hemoglobin:

Oxygen content

$$(\text{mL } O_2 / \text{L}) = \left[\frac{(\text{Oxygen capacity} \times \text{Sp}O_2) + }{(pO_2 \times 0.003 \text{ mL/mm Hg/dL})} \right] \times 10 \text{ dL/L}$$

In room air, one typically uses only the oxygen content of *hemoglobin* for calculations instead of the total oxygen content of the *blood*, due to the fact that dissolved oxygen contributes very little. The use of the expanded formula for oxygen content in calculations is mandatory in the patient with (or without) a left-to-right shunt in whom the hemodynamic study is repeated in 100% oxygen in order to determine pulmonary vasoreactivity. If dissolved oxygen is not accounted for in flow calculations, the amount of flow/shunt may be overestimated. Conversely, the resistance estimated based on these flow calculations will be *underestimated*, a very important issue for decisions that are made based on the data obtained.

For example, if the hemoglobin is 11.5 g/dL, the femoral artery oxygen saturation is 99%, and the PaO_2 is 106 mm Hg, the oxygen content is calculated as follows:

$$\begin{aligned} \text{Oxygen capacity} &= 11.5 \text{ g / dL} \times 1.36 \text{ mL / g} \\ &= 15.6 \text{ mL } O_2 / \text{dL blood} \end{aligned}$$

$$\begin{aligned} \text{Dissolved oxygen} &= 106 \text{ mm Hg} \times 0.003 \text{ mL / mm Hg / dL} \\ &= 0.32 \text{ mL } O_2 / \text{dL blood} \end{aligned}$$

$$\begin{aligned} \text{Oxygen content} &= [(15.6 \text{ mL / dL} \times 0.99) + 0.32 \text{ mL / dL}] \\ &\quad \times 10 \text{ dL / L} = 154 + 3.2 \\ &= 157 \text{ mL } O_2 / \text{L blood} \end{aligned}$$

Figure 12.5. Oxygen consumption curves (boys, in mL/min).

If the femoral artery PaO_2 is 566 and the oxygen saturation is 100%, the oxygen content is calculated as follows:

$$\begin{aligned}\text{Oxygen capacity} &= 11.5 \text{ g/dL} \times 1.36 \text{ mL/g} \\ &= 15.6 \text{ mL O}_2 / \text{dL blood}\end{aligned}$$

$$\begin{aligned}\text{Dissolved oxygen} &= 566 \text{ mm Hg} \times 0.003 \text{ mL/mm Hg/dL} \\ &= 1.70 \text{ mL O}_2 / \text{dL blood}\end{aligned}$$

$$\begin{aligned}\text{Oxygen content} &= [(15.6 \text{ mL/dL} \times 1.0) + 1.70 \text{ mL/dL}] \\ &\quad \times 10 \text{ dL/L} = 156 + 17 \\ &= 173 \text{ mL O}_2 / \text{L blood}\end{aligned}$$

Oxygen Method for Calculation of Cardiac Output

When cardiac output is calculated using the Fick method, the indicator is oxygen. The rate of change of the indicator is the oxygen consumption (VO_2). It is assumed that measurements are taken at a steady-state condition; thus VO_2 by tissues equals oxygen uptake by the lungs. VO_2 may be measured or assumed. In the current era, it is most common to use the assumed values for purposes of calculations because the actual measurement of VO_2 is quite cumbersome. It is often difficult to maintain a steady state in the pediatric patient in order to measure a reliable VO_2 . Furthermore, measurement of VO_2 requires spontaneous respirations, and since procedures are often performed under

general anesthesia, this measurement would have to be performed at a different time than when the oxygen saturation samples are being obtained. Assumed values that are most often used for calculations are based on the formulas of Lafarge and Meittinen (19) and are derived from measurements made in 879 patients using the Douglas bag method. Values for patients 3 to 18 years of age and at various heart rates are listed in Figures 12.5 and 12.6.

There are specific equations for applying the Fick principle to the calculation of the systemic and pulmonary flow (Table 12.2). Possible sources of error include inaccuracy of the value used for oxygen consumption, inaccurate sample for the mixed venous saturation, and absence of a steady-state condition.

The systemic flow (Q_s) is equal to the VO_2 divided by the change in oxygen content across the body (oxygen content of the aorta minus the SVC).

$$Q_s = \text{VO}_2 / (\text{oxygen content of aorta} - \text{oxygen content of SVC})$$

If the patient is breathing room air, the amount of dissolved oxygen can be ignored, simplifying the equation to:

$$\begin{aligned}Q_s &= \text{VO}_2 / [\text{hemoglobin} \times 1.36 \times 10 \\ &\quad \times (\text{aorta sat} - \text{SVC sat})]\end{aligned}$$

Similarly, the pulmonary flow (Q_p) is equal to the VO_2 divided by the change in oxygen content across the lungs (oxygen content of the pulmonary vein minus oxygen content of the pulmonary artery).

Oxygen Consumption by Age (Girls)

Figure 12.6. Oxygen consumption curves (girls, in mL/min).

$$Q_p = \frac{VO_2}{(\text{pulm vein oxygen content} - \text{pulm art oxygen content})}$$

And if ignoring dissolved oxygen:

$$Q_p = \frac{VO_2}{[\text{hemoglobin} \times 1.36 \times 10 \times (\text{pulm vein sat} - \text{pulm art sat})]}$$

It is important to remember the units assigned to each factor in these equations. The unit for cardiac output is L/min. The unit for VO_2 is mL O_2 /min. Oxygen content is measured as mL O_2 /L of blood. Though not illustrated in the above equations, final flow index in children is normally reported as cardiac index, which is obtained by dividing the output by the patient's body surface area (BSA) given in m^2 . Since flows are indexed to BSA, inaccurate measurement of patient length, especially in infants, may be another source of error. Note: if the final VO_2 value that is used in this formula is not indexed to BSA, the final cardiac output calculation is divided by the BSA to index the value accordingly. This correction does not need to be done if the VO_2 is already indexed! The factor of 10 in the denominator converts the value from g/dL to g/L in order to report the cardiac index value in L/min/ m^2 .

Thermodilution Method

With the thermodilution method, the indicator is temperature. A double-lumen thermodilution (Swan-Ganz) catheter is used. A bolus of cold saline of a known temperature (room

temperature, $\sim 21^\circ\text{C}$) is injected through the proximal port (positioned in the right atrium). A thermistor for measuring temperature is located near the catheter tip (positioned in the pulmonary artery). Saline cools the blood as they mix together; the degree of cooling of the blood is inversely proportional to the magnitude of flow and directly proportional to several factors: the volume of saline injected, the temperature difference between the injectate and the blood, and the specific heats of the injectate and the blood. The thermodilution cardiac output measurement is an automated system (including the injector) and the calculations are performed by a computer. To minimize error, three to five sequential injections of cold saline are performed over 1 to 2 minutes. The technique is simple, precise, and easily allows serial measurements to compare interventions in the cath lab or intensive care unit. The thermodilution method (as with any indicator dilution method) requires complete mixing; thus, it is most accurate when there is a mixing chamber proximal to the thermistor (i.e., the right ventricle). The thermodilution method is used in patients who do not have intracardiac or great vessel level shunts or significant tricuspid/pulmonary valve insufficiency. Possible sources of error include inconsistent volume of injectate, variable temperature of the blood or injectate, apposition of the thermistor to a vessel wall, and inadequate mixing. Thorough mixing is particularly problematic in venous systems with low flow (e.g., bidirectional cavopulmonary anastomosis, Fontan circulation). This method of determining cardiac output is less frequently used in the congenital cardiac patient because of all of these factors.

TABLE 12.2 Commonly Used Equations for Calculating Flow, Resistant, and Shunt

Oxygen capacity

$$\text{O}_2 \text{ Capacity (mL O}_2\text{/dL)} = \text{Hemoglobin (g/dL)} \times 1.36$$

Dissolved oxygen

$$\text{Dissolved O}_2 \text{ (mL O}_2\text{/dL)} = 0.003 \times \text{pO}_2 \text{ (mm Hg)}$$

Oxygen content

$$\text{O}_2 \text{ content (mL O}_2\text{/L)} = [(\text{O}_2 \text{ Capacity} \times \text{SpO}_2) + \text{Dissolved O}_2] \times 10$$

Systemic blood flow

$$Q_s = \frac{\text{VO}_2}{\text{SAO}_2 \text{ Content} - \text{MVO}_2 \text{ Content}}$$

Pulmonary blood flow

$$Q_p = \frac{\text{VO}_2}{\text{PVO}_2 \text{ Content} - \text{PAO}_2 \text{ Content}}$$

Q_p/Q_s estimation

$$Q_p/Q_s = \frac{\text{Aosat} - \text{SVC sat}}{\text{PV sat} - \text{PA sat}}$$

Effective systemic/pulmonary blood flow

$$Q_{ES} = Q_{EP} = \frac{\text{VO}_2}{\text{PVO}_2 \text{ Content} - \text{MVO}_2 \text{ Content}}$$

Shunt volume

$$Q_{L-R} = Q_p - Q_{EP} \quad Q_{L-R} = Q_p - Q_{EP}$$

Shunt percentage

$$\text{Shunt}_{L-R} = \frac{Q_p - Q_{EP}}{Q_p} = 1 - \frac{\text{PV sat} - \text{PA sat}}{\text{PV sat} - \text{MV sat}}$$

$$\text{Shunt}_{R-L} = \frac{Q_s - Q_{ES}}{Q_s} = 1 - \frac{\text{Aosat} - \text{MV sat}}{\text{PV sat} - \text{MV sat}}$$

Systemic vascular resistance

$$R_s = \frac{\text{pAo}_{\text{mean}} - \text{pRA}_{\text{mean}}}{Q_s}$$

Pulmonary vascular resistance

$$R_p = \frac{\text{pPA}_{\text{mean}} - \text{pLA}_{\text{mean}}}{Q_p}$$

pO₂, partial pressure of oxygen; VO₂, oxygen consumption (mL O₂/min); Q_s, systemic blood flow in (L/min); SA, systemic arterial; MV, mixed venous; Q_p, pulmonary blood flow (L/min); PV, pulmonary vein; PA, pulmonary artery; Q_{ES}, effective systemic blood flow; Q_{EP}, effective pulmonary blood flow; Q_{L-R}, left-to-right shunt volume (L/min); Q_{R-L}, right-to-left shunt volume (L/min); Shunt_{L-R}, left-to-right shunt percentage; Shunt_{R-L}, right-to-left shunt percentage; R_s, systemic vascular resistance (Wood units); pAo_{mean}, mean aortic pressure; pRA_{mean}, mean right atrial pressure; R_p, pulmonary vascular resistance (Wood units); pPA_{mean}, mean pulmonary artery pressure; pLA_{mean}, mean left atrial pressure.

Intracardiac Shunts

For practical purposes, it is assumed that with normal cardiovascular connections, the oxygen saturation in all right heart structures (i.e., SVC, right atrium, right ventricle, and pulmonary artery) would be equal. Similarly, the oxygen saturation in the left heart structures (pulmonary veins, left atrium, left ventricle, and aorta and its branches) would be equal.

In reality, oxygen saturation varies between the SVC and coronary sinus, and complete mixing does not occur until systemic venous return reaches the pulmonary artery. An increase in oxygen saturation between different sites of the right heart would give precise information on the location and magnitude of left-to-right shunts, whereas a decrease in saturation between successive chambers of the left heart would define a right-to-left shunt.

To evaluate possible intracardiac shunts in the cath lab, it is necessary to understand four assumptions inherent in these calculations and to be certain they are applicable. The first assumption is that the patient is at steady state. While this may be true if the patient is asleep or resting quietly, as conditions change during the measurements, errors may be introduced. Therefore, it is best to obtain all samples as rapidly and safely possible to minimize perturbations in patient steady state. The second assumption is that an oxygen saturation sample is an accurate representation of the chamber or vessel. This is often the case, but oxygenation sampling is fraught with difficulty; scattered areas of pulmonary parenchymal disease or atelectasis may lead to inhomogeneous oxygenation of pulmonary artery flow. Similarly, the right atrium is a difficult site for obtaining a representative sample because of streaming from the highly saturated renal vein, the less saturated hepatic vein, and the very low saturated coronary sinus. Inferior vena cava saturation is usually higher at rest than the SVC saturation, but during general anesthesia, the SVC saturation may be higher. The third assumption is that all blood entering a chamber does so in an antegrade fashion, and, therefore, the sample is not “contaminated” by blood from a distal chamber. Certainly, this is not the case when there is atrioventricular or semilunar valve regurgitation. For example, a right ventricle saturation may be falsely elevated when there is pulmonary regurgitation and a patent ductus arteriosus. The fourth assumption is that the patient’s hemodynamic state in the cath lab represents the baseline hemodynamic state. This is probably the most difficult assumption to support; at one end of the spectrum, inadequate sedation results in a terrified or combative child, while at the other end of the spectrum is general anesthesia. Neither condition represents a normal physiologic state. The best an operator can do is to establish the conditions of the cardiac catheterization, then maintain these same conditions in a “steady state” until a complete set of measurements has been obtained.

Quantitative Assessment of Shunts

Use of the Fick principle to calculate pulmonary flow (Q_p) and systemic flow (Q_s) has been discussed. Calculation of left-to-right and right-to-left shunts requires understanding the concept of *effective* pulmonary flow (Q_{ep}) and *effective* systemic flow (Q_{es}). The formulas discussed subsequently are also presented in Table 12.2. The Q_{ep} is the volume of systemic venous return (i.e., “blue” blood) that flows to the lungs to be oxygenated. Q_{ep} is calculated by using the oxygen saturation of the “red” blood flowing out of the lungs (pulmonary vein) minus the saturation of the “blue” blood flowing into the lungs (SVC) using the following equation:

$$Q_{ep} = \text{VO}_2 / [\text{hemoglobin} \times 1.36 \times 10 \times (\text{pulm vein sat} - \text{SVC sat})]$$

Therefore, if the patient has no left-to-right shunt, the mixed venous saturation and pulmonary artery saturation are the same, and all of the pulmonary blood flow is “effective,” that is Q_p = Q_{ep}.

The Q_{es} is the volume of pulmonary venous return (i.e., “red” blood) that flows to the body. For all patients in a steady hemodynamic state:

$$Q_{ep} = Q_{es}$$

Simply stated, the amount of “blue” blood that flows to the lungs is equal to the amount of “red” blood that flows to the body.

When there is a left-to-right shunt, some oxygenated blood recirculates through the lungs, thus $Q_p > Q_{ep}$. The volume of a left-to-right shunt is the difference between the total pulmonary flow (Q_p) and the effective pulmonary flow (Q_{ep}):

$$Q_{L-R} = Q_p - Q_{ep}$$

Similarly, when there is a right-to-left shunt, some of the deoxygenated “blue” blood bypasses the lungs and recirculates through the body, thus $Q_s > Q_{es}$. The volume of a right-to-left shunt is the difference between the total systemic flow (Q_s) and the effective systemic flow (Q_{es}):

$$Q_{R-L} = Q_s - Q_{es}$$

Since $Q_{ep} = Q_{es}$, then:

$$Q_{R-L} = Q_s - Q_{ep}$$

Mathematically, the ratio of pulmonary flow to systemic flow is Q_p/Q_s . Calculating the Q_p/Q_s is simple and can be done immediately once the appropriate saturation samples are obtained when assessing shunt lesions. Since the oxygen consumption is in the numerator of both the Q_p and Q_s equations, it cancels out, leaving the following equation:

$$Q_p / Q_s = \frac{\text{systemic A - V oxygen difference}}{\text{pulmonary A - V oxygen difference}}$$

If the patient is breathing room air, dissolved oxygen is negligible, and the calculation of Q_p/Q_s can be stated in terms of oxygen saturation samples as follows:

$$Q_p / Q_s = \frac{(\text{Aorta sat} - \text{SVC sat})}{(\text{pulm vein sat} - \text{pulm art sat})}$$

When the pulmonary blood flow is markedly increased (e.g., pulmonary artery saturation 89%), the difference in pulmonary vein and pulmonary artery saturation is small (e.g., 99% to 89%), so the normal error of 2% to 3% that may occur with each measurement becomes significant. Thus, when there is a large left-to-right shunt, the Q_p/Q_s is simply reported as “greater than 3:1.”

Qualitative Assessment of Shunts

During right heart catheterization, some degree of variability in oxygen saturation from one chamber to the next is expected, typically between 1% and 2% from sample to sample. In a seminal study from 1979, Freed et al. investigated the normal variation between oxygen samples throughout the right heart in over 1,000 catheterizations in children with aortic or pulmonic stenosis who had no intracardiac shunts (confirmed by dye curves or angiography) (20). The mean oxygen saturations were similar in the SVC, right atrium, right ventricle, and pulmonary artery. The oxygen saturation sample in the proximal chambers was subtracted from the pulmonary artery sample to determine the variability in the absence of a left-to-right shunt. The standard deviation of the pulmonary artery and SVC difference was 2.9%, that of the pulmonary artery and right atrium difference was 1.8%, and that of the pulmonary artery–right ventricle difference was 1.8%. Thus, in the absence of a shunt, a step-up of >6% at the atrial level, 4% at the ventricular level, and 4% at the great vessel level will occur <5% of the time (i.e., twice the standard deviation).

Increases of >9%, 6%, and 6%, respectively (i.e., three times the standard deviation), would be expected no more than 1% of the time, thus would be highly unlikely in the absence of intracardiac shunting. Qualitatively, if there is a step-up in oxygen saturations in the right heart, there is a left-to-right shunt. Conversely, there is a right-to-left shunt if there is a step-down in oxygen saturations in the left heart. Quantitative methods are discussed later in the chapter, and must be used if one wants to define the caliber of the shunt.

The sample in the true SVC is taken in the mid-portion, superior to the entrance of the azygous vein and inferior to the innominate vein (both of which may have a higher saturation than the mid-SVC). Sampling too high in the SVC, near the IJ vein, will provide a “falsely” low value for mixed venous saturation use in calculations because of cerebral extraction. However, general anesthesia can also result in a higher than normal SVC saturation. High mid-SVC saturation also may be seen in the presence of a high-output state, partial or total anomalous pulmonary venous return to the SVC or innominate vein, or an arteriovenous fistula. A low mid-SVC saturation may be present when the systemic arterial saturation is low (pulmonary venous desaturation, right-to-left shunt) or with a low cardiac output state (high tissue extraction).

The right atrial sample should be obtained at the lateral midatrial wall to avoid the low saturation stream from the coronary sinus and to facilitate mixing from the inferior and superior venae cavae streams. A step-up of >9% is highly suggestive of a left-to-right shunt from an atrial septal defect, anomalous pulmonary venous connection, a left ventricle-to-right atrium shunt, a ventricular septal defect with tricuspid insufficiency, or a shunt from the aorta (ruptured sinus of Valsalva aneurysm, coronary artery fistula). However, the absence of a significant step-up in the right atrium does not completely rule out a left-to-right shunt.

The right ventricular saturation should be approximately equal to that in the right atrium; a step-up of >6% suggests a left-to-right shunt. A step-up at the ventricular level may be seen with a low atrial septal defect (where the oxygenated blood preferentially streams into the right ventricle), a ventricular septal defect, a ruptured sinus of Valsalva aneurysm, a coronary AV fistula draining into the right ventricle, or a left-to-right shunt at the great vessel level with significant pulmonary valve insufficiency.

A step-up of >6% at the pulmonary artery level is seen with a high outlet ventricular septal defect, patent ductus arteriosus, aortopulmonary window, coronary artery fistula into the pulmonary artery, anomalous origin of the coronary artery from the pulmonary artery also with fistula, or a surgical aortopulmonary communication.

Similar data for the qualitative detection of right-to-left shunts are not available. If the aortic saturation is <92% (sea level, normal ventilation) or if there is >3% decrease in oxygen saturation on the left side of the heart, a right-to-left shunt is likely present. Pulmonary vein desaturation results most commonly from hypoventilation (sedation), pulmonary parenchymal disease, or pulmonary edema. Administering 100% oxygen will increase the pulmonary vein saturation and the systemic artery saturation, allowing one to distinguish between pulmonary parenchymal disease and a right-to-left shunt. Pulmonary vein desaturation that does not resolve with administration of 100% oxygen suggests an intrapulmonary shunt, such as from a pulmonary arteriovenous malformation. Left atrial desaturation, with normal pulmonary vein saturation, usually results from a right-to-left shunt through an atrial septal defect or PFO. This is a necessary shunt with tricuspid atresia and is seen frequently with tricuspid stenosis, Ebstein anomaly of the tricuspid valve, pulmonary atresia or severe pulmonic stenosis, or severe pulmonary vascular disease. Right-to-left atrial shunt may be seen with any disease

that markedly decreases right ventricular compliance or leads to right ventricular failure. Occasionally, right-to-left atrial shunting can occur even in the presence of normal right-sided pressures and resistances. This condition, called platypnea-orthodeoxia syndrome, produces cyanosis and dyspnea, which is due to cyanosis from right-to-left shunting across a PFO as one changes position from supine to sitting. A rare congenital defect, a persistent left SVC to the left atrium, also can cause left atrial desaturation.

Left ventricular desaturation may occur with any lesion that produces desaturation in the pulmonary veins or left atrium. Right-to-left shunting at the ventricular level occurs when the right ventricular systolic pressure is equal to or greater than left ventricular systolic pressure (e.g., a ventricular septal defect and elevated pulmonary vascular resistance or right ventricular outflow tract obstruction). Right-to-left shunting can occur during diastole if the right ventricular diastolic pressure exceeds that of the left ventricle, even if the right ventricular systolic pressure is less than that of the left ventricle. Occasionally, the streaming effect of a right-to-left shunt through a ventricular septal defect is such that the desaturation is not detected at the ventricular level but is detected in the ascending aorta (e.g., tetralogy of Fallot).

A decrease in oxygen saturation between the left ventricle and aorta requires both a communication between the aorta and the pulmonary artery and increased pulmonary vascular resistance. Typically, this is a patent ductus arteriosus or aortopulmonary window, combined with either pulmonary vascular obstructive disease or peripheral pulmonary stenosis. A decrease in saturation from the ascending to the descending aorta occurs with the combination of a patent ductus arteriosus and coarctation of the aorta; this right-to-left shunt from the pulmonary artery to the descending aorta causes differential cyanosis—saturated, pink upper extremities and desaturated, blue lower extremities.

Equal oxygen saturations in the aorta and pulmonary artery occur with lesions that cause complete mixing at any level. Occasionally, even when complete mixing is expected, different saturations may be found in the pulmonary artery and aorta due to intracardiac streaming patterns. For example, most patients with truncus arteriosus have preferential streaming, resulting in lower saturation in the pulmonary artery and higher saturation in the aorta.

In children who have transposition of the great arteries with intact ventricular septum, the pulmonary artery saturation is always higher than the aortic saturation, defining “transposition physiology.” With transposition of the great arteries and a large ventricular septal defect, there may be complete mixing, thus equal saturations in the pulmonary artery and aorta, but in some patients, streaming may still produce less favorable mixing, thereby increasing the importance of atrial level mixing in these patients to improve aortic saturations. If the saturation in the descending aorta is higher than that in the ascending aorta, the child has transposition of the great arteries with a patent ductus arteriosus and coarctation of the aorta (or interrupted aortic arch), causing reversed differential cyanosis—desaturated, blue upper extremities and saturated, pink lower extremities.

Vascular Resistance

Cardiac catheterization may be needed in children to assess pulmonary vascular resistance in order to determine operability or to plan therapy (e.g., in the setting of primary pulmonary hypertension). It is crucial that the data used for this calculation are collected meticulously, calculations are performed correctly, and the limitations of the resultant value are appreciated. The basic formula for vascular resistance shows us that resistance is related to the pressure drop across the vascular

bed divided by the flow across the vascular bed. Mathematical assessment of vascular resistance is based on laws of Poiseuille and Ohm (which describes electrical resistance). Poiseuille's law states that the resistance to flow across a vascular bed is related to the difference in mean pressure at inflow to outflow divided by the amount of flow. Neither concept perfectly describes a biologic system for several reasons. Blood flow is pulsatile (i.e., not constant) and not laminar, vascular walls are distensible (not rigid), and blood is not a homogeneous fluid. In addition, vascular resistance is not a fixed entity; it is a dynamic set of blood vessels changing in response to numerous mechanical and neurohormonal factors. Adapting these equations and applying them to the vascular bed results in the currently used simplified equation for calculation of vascular resistance (R):

$$R = \Delta P / Q$$

where

ΔP = change in pressure across the vascular bed

Q = flow in the vascular bed

Specific formulas for vascular resistance are found in Table 12.2. One can see from this formula, if rearranged as $R \times Q = \Delta P$, that increases in pressure difference (ΔP) across a vascular bed may be due either to resistance (R) or flow (Q) or both. Normal values for vascular resistance have been developed, and it is against these values that any one patient's hemodynamic situation is compared.

For example, if a sedated patient in the cath lab is hypoventilated, hypercarbia and acidosis develop; both factors cause an elevation of pulmonary vascular resistance. Another important factor affecting pulmonary resistance is pulmonary capillary recruitment that requires a minimal distending pressure. When there is decreased pulmonary flow or pressure (e.g., tetralogy of Fallot, restrictive aortopulmonary shunt, cavopulmonary anastomosis), there is derecruitment of capillaries in the pulmonary vasculature, resulting in an elevated resistance (21). There is no method to predict if (and how much) the pulmonary resistance will decrease with increased flow or pressure. Nevertheless, the concept of vascular resistance is very important in managing patients with congenital heart defects.

The pulmonary vascular resistance (R_p) equation is

$$R_p = \Delta \text{ Pulmonary pressure} / \text{Pulmonary blood flow}$$

where Δ pulmonary pressure is the change in pressure across the pulmonary vascular bed (i.e., pulmonary artery mean pressure – left atrial mean pressure), often called the transpulmonary gradient.

Similarly, the equation for systemic vascular resistance is

$$R_s = \Delta \text{ Systemic pressure} / \text{Systemic blood flow}$$

where Δ systemic pressure is the change in pressure across the systemic vascular bed (i.e., systemic arterial mean pressure – right atrial mean pressure).

When assessing the pulmonary vascular reactivity to various medications, a drop in pulmonary pressure may be related to the medicine decreasing the systemic resistance. In such situations, calculating the relative resistances of the pulmonary and systemic vasculature may provide useful information:

$$R_p / R_s = \text{Pulmonary vascular resistance} / \text{Systemic vascular resistance}$$

This “hybrid” vascular resistance unit, the Wood unit, is defined in mm Hg/L/min; it is used for pediatric hemodynamic calculations. Because of the considerable size range of pediatric patients, Wood units are indexed to BSA by *multiplying* by the BSA and are reported as “Wood units·m²” (mm Hg/L/min·m²). Indexing these units allows for comparison between patients

of different sizes (22). The normal range for indexed pulmonary resistance is 1 to 3 Wood units·m². The normal range for indexed systemic resistance is 20 to 28 Wood units·m².

When calculating the pulmonary vascular resistance in patients with normal pulmonary artery pressures, the numerator (i.e., Δ pressure) is a small number (4 to 10 mm Hg), similar in magnitude to the denominator (i.e., the pulmonary blood flow, 2 to 8 L/min). Thus, a 1- to 2-mm Hg error in pressure measurement can result in a large error in the calculated R_p . Thus, it is crucial to make sure the pulmonary artery and left atrial pressures are measured accurately. If there is concern for measurement error, recalibrate or change transducers to verify the pressures obtained.

Oxygen and Nitric Oxide Inhalation Studies

For patients with pulmonary hypertension, it is not only important to calculate pulmonary vascular resistance but also to identify whether elevated pulmonary vascular resistance is fixed or reactive to certain pharmacologic interventions. To answer this question in the cardiac cath lab, patients who have elevated pulmonary vascular resistance are given 100% inhaled oxygen or nitric oxide (usually 20 to 80 ppm). These drugs have pulmonary vasodilatory effects as is discussed in Chapter 20. Hemodynamic measurements (and baseline calculations) are performed first in room air and then repeated after giving oxygen and/or nitric oxide for several minutes. Patients with elevated pulmonary vascular resistance that is fixed may not exhibit a significant increase in left-to-right shunt (if present) or significant decrease in resistance after receiving oxygen or nitric oxide. On the other hand, patients with reactive pulmonary hypertension will show a significant decrease in pulmonary vascular resistance index and R_p/R_s (23).

Valve Area and Pressure Gradient

The pressure gradient across a valve is a function of both the flow across the valve and the orifice size. At normal flow rates, cardiac valves offer little resistance to flow. As the flow increases, a small pressure gradient may develop across a normal valve (e.g., a large left-to-right shunt through a ventricular septal defect resulting in a flow gradient across a normal pulmonary valve). Conversely, at low flow rates (e.g., shock), there may be little pressure gradient across a severely obstructed valve (e.g., neonatal critical aortic stenosis). Adult cardiologists describe valve stenosis in terms of the valve area, rather than the pressure gradient, as the valve area calculation takes into consideration flow rate. In general, the orifice area for most valves is 2.5 cm². However, most pediatric cardiologists describe valve gradients in terms of the peak pressure gradient across the valve. These pressure gradients are meaningful only when considered in conjunction with the transvalvar flow or cardiac output.

Valve area is calculated using the Gorlin formula (Table 12.3) that incorporates cardiac output, heart rate, and pressure curves on either side of the stenotic lesion (incorporating time lines, in order to calculate systolic ejection or diastolic filling time, and calibrated for pressure) (24). Flow across a valve is not continuous throughout the cardiac cycle. Flow occurs across the aortic and pulmonary valves, in systole, and across the mitral and tricuspid valves in diastole. The systolic ejection time is the period during which the aortic valve is open and blood is flowing across the valve and it is determined from simultaneous pressure tracings of the left ventricle and ascending aorta. The two points at which the ventricular tracing crosses the aortic tracing represent the opening and closing of the aortic valve. The time between these points is the systolic ejection time. The diastolic filling period is the time during which the mitral valve is open and blood is flowing across the valve. It is determined from simultaneous pressure tracings of the left atrium and left ventricle. The two points at which the left ventricular tracing

TABLE 12.3 Calculation of Valve Areas Using the Gorlin Formula

Calculation of the aortic valve area:

Determine cardiac output (in mL), systolic ejection time (in s/beat), and R-R interval (in seconds).

Calculate systolic flow:

$$\text{Systolic flow} = \frac{\text{cardiac output} \times \text{R-R interval}}{60 \times \text{systolic ejection time}}$$

Determine mean aortic valve gradient (mm Hg, by planimetry):

$$\text{Aortic valve area (cm}^2\text{)} = \frac{\text{systolic flow}}{44.5 \times \sqrt{\text{mean systolic gradient}}}$$

Calculation of mitral valve area:

Determine cardiac output (in mL), diastolic filling time (in s/beat), and R-R interval (in seconds).

Calculate diastolic flow:

$$\text{Diastolic flow} = \frac{\text{cardiac output} \times \text{R-R interval}}{60 \times \text{diastolic filling time}}$$

Determine mean mitral valve gradient (mm Hg, by planimetry):

$$\text{Mitral valve area} = \frac{\text{Diastolic flow}}{37.8 \times \sqrt{\text{mean diastolic gradient}}}$$

crosses the left atrial tracing represent the opening and closing of the mitral valve. The time between these points is the diastolic filling period. Because the left atrium is rarely directly entered except in the presence of an atrial septal defect or PFO, it is more common to utilize simultaneous pressure tracings of the left ventricle and the pulmonary artery capillary wedge. These tracings must be realigned to compensate for the time delay of the pulmonary wedge tracing. In adult patients (who have slower heart rates), the wedge tracing is delayed by 50 to 70 ms; in pediatric patients (who have faster heart rates), the wedge tracing is moved to the left so that the v wave is bisected by or just precedes the downstroke of the left ventricular tracing. Once the appropriate ejection or filling period is determined, flow across the valve is calculated from the Gorlin equation according to the formulas provided in Table 12.3.

The mean aortic valve gradient is most accurately determined by planimetry of the area between the left ventricular and aortic tracings during the systolic ejection time. The mean mitral valve gradient is most accurately determined by planimetry of the area between the left ventricular and the left atrial (or pulmonary capillary wedge) tracings during the diastolic filling period. Previously, planimetry was done by manual tracing or averaging multiple parallel lines; now computer programs easily perform planimetry.

In patients with congenital heart defects, particularly intracardiac or extracardiac shunts, determining the valve area is challenging, as the flow may be different across each valve. For example, with a ventricular septal defect, flow across the mitral valve is greater than flow across the aortic valve as a portion of left ventricular preload is ejected across the defect rather than the aortic valve. When the flow across a valve cannot be accurately determined, the valve area cannot be calculated. However, most of this information can be obtained from noninvasive means such as detailed 2-D and Doppler echocardiography.

ANGIOGRAPHY

Basic Concepts

In this era of highly developed noninvasive imaging techniques, the role of cardiac and vascular angiography is complementary and remains essential for the evaluation and management of selected conditions. The goals of angiography should be defined prior to the procedure, as determined by the information that is available from noninvasive studies, such as echocardiography, magnetic resonance imaging, and computer tomographic imaging, and further delineated during the procedure based on the hemodynamic and oximetric data obtained.

This section covers basic angiography issues, including contrast agents, radiation exposure, catheters, and camera angles. Angiographic imaging of selected defects is discussed.

Contrast Media

Contrast media are radiopaque due to the iodine content and classified as either ionic (high osmolality) or nonionic (low osmolality) compounds. Both types yield excellent image quality but have widely different side effect profiles. The main hemodynamic and cardiovascular effects of contrast agents are directly related to osmolality, sodium content, and the agent's effect on serum calcium. For this reason, it is important to measure the most important portion of the hemodynamic data prior to use of a significant amount of contrast.

The relative advantages and disadvantages of ionic versus nonionic contrast media have been discussed extensively in the literature (25). Ionic media are generally not recommended for use in the pediatric patient due to their more significant adverse physiologic and hemodynamic effects. The effects of using ionic media include: a rapid shift of interstitial and intracellular fluid into the vascular space, binding of serum calcium, an increase in pulmonary artery and left atrial pressures, reflex tachycardia, a sensation of intense heat or pain, coughing (pulmonary artery injection), and the potential for exacerbation of pulmonary hypertension. Nonionic media are routinely used for the pediatric or complex congenital patient, as these agents are safer, well tolerated, but more expensive. The older published guidelines for maximum contrast dosage typically state a maximum of 4 mL/kg as a limit for routine angiography during a procedure; however, studies using the newer contrast agents (with lower side effect profile) have not been conducted (26). It is prudent to assure that each patient receives adequate hydration during and after the catheterization procedure.

Allergic reactions to contrast agents are unusual without prior exposure. If a patient has had a known allergic reaction to contrast, a premedication regimen that includes administration of a corticosteroid and antihistamine should be utilized. Careful observation for any allergic reaction in such patients following injection of a very small dose of contrast should be performed before administering a bolus of contrast for angiography. Repeat dosing of these medications may be necessary depending on the length of the procedure. Allergy to shellfish may portend sensitivity to iodine, which is usually present in contrast media.

Radiation Dose and Exposure

Compared with other diagnostic procedures performed in pediatric patients, cardiac catheterization produces a relatively large dose of radiation. In adults, the cardiac catheterization radiation dose is about 600 times the dose of a chest x-ray view (27). Pediatric patients undergoing complex diagnostic

evaluation or therapeutic cardiac catheterization are typically exposed to longer fluoroscopy times, thus a higher radiation dose. Thus, it is imperative that the catheterization goals be defined as well as possible ahead of time to minimize the exposure to radiation. For certain complex conditions (e.g., pulmonary atresia, complex functional single ventricle physiology), an increasingly aggressive treatment approach may result in an increased number of catheterizations at an earlier age, particularly in those patients who need intervention. Although it is difficult to quantitate the risk from radiation exposure in the cath lab, the probability of a fatal cancer per fluoroscopically guided procedure has been reported at approximately 0.07% (28).

Factors that affect the radiation dose include the duration of exposure, the BSA exposed, and the current (mA) and voltage (kV) used to generate the image. Although the patient's risk associated with the radiation exposure should be less than that associated with untreated congenital heart defects or incomplete diagnosis, the cardiologist must be aware of issues that affect both the patient and staff exposure to radiation, doing everything possible to minimize this exposure. As technology has advanced, technical modifications that have reduced radiation exposure during cardiac catheterization include the transition to digital-only systems, high-power x-ray tubes that allow copper filtration (inserted to reduce skin dose), last image storage, and improved detector efficiency (28,29).

Patient Dose

Cineangiography is associated with a markedly higher radiation dose per unit time than fluoroscopy, typically about 15 times higher (29,30). Thus, in a simple diagnostic catheterization, cineangiography accounts for most of the radiation exposure. However, in lengthy interventional cases, fluoroscopy time contributes significantly to the total radiation dose. Simultaneous biplane imaging (either with fluoroscopy or cineangiography) doubles the radiation dose compared with single-plane imaging. Similarly, the radiation dose increases with frame rate; pulsed fluoroscopy at 30 frames per second is twice the dose of pulsed fluoroscopy at 15 frames per second. For basic catheter manipulation, the fluoroscopic frame rate can be set lower, if extensive procedure time is anticipated; however, this will detract from image quality. By selecting the lowest frame rate necessary (fluoroscopy and cineangiography) and judiciously minimizing the use of biplane fluoroscopic imaging, the cardiologist can significantly reduce the radiation dose to the patient and cath lab personnel. One must always balance radiation dose with image quality (29).

Recent improvements in cath lab equipment also have reduced the radiation dosage. In particular, the use of digital flat panel imaging systems has decreased the radiation dosage from 25% to 50% when compared to prior use of conventional film systems (28). Collimation of the x-ray beam is another important factor in reducing radiation exposure. When the beam is collimated to the smallest area needed to view the pertinent structures, there is not only reduction in the volume of patient tissue exposed and radiation scatter to personnel, but there is improvement in image quality. Current modern systems allow for virtual collimation based on the last image stored, so that additional exposure is not needed to set these fields (28). Wedge filters should be positioned in the corners of the radiographic field to further improve image quality, but should not be considered a major strategy for reduction of radiation exposure. One must remember that electronic magnification modes will increase patient radiation dosage, so it is recommended that the lowest level of magnification that provides good image quality be used (29).

Cath Lab Personnel Exposure

The previous discussion of radiation exposure is not only relevant to the patient but to the staff in the cath lab. The following considerations also apply to the protection of personnel.

Scatter of the x-ray beam is the major source of personnel exposure in the cath lab, although as a general rule the intensity of scatter to the operator is 1/1,000 of the patient skin dose. It is approximately 10 times greater with cineangiography than with fluoroscopy. Increasing patient size, field size, and angled views will all increase scatter. Lead shielding and increased distance from the patient provide the best protection against exposure from x-ray scatter; the radiation dose decreases rapidly as one moves away from the patient ($1/r^2$) (27). Distance from the patient is more easily maximized during angiography when using an automatic injector system, thereby reducing exposure. The operators' hands should not be seen in the x-ray field (29).

All staff working in the cardiac cath lab must wear "lead" aprons. New aprons, which are not made of lead, can be as much as 50% lighter than a lead apron, making them more comfortable to wear and producing less fatigue. They are made from several layers of very light fabric; each layer absorbs a different wavelength of radiation but covers the same radiation spectrum as a lead apron. Those personnel likely to have their backs to the patient during the procedure (e.g., staff obtaining equipment, performing transesophageal echocardiography) should wear lead aprons that completely wrap around them. A thyroid collar reduces the exposure risk to the thyroid by approximately one half. Wraparound leaded eyeglasses reduce ocular exposure by approximately one-fifth. Regular eyeglasses with glass lenses provide some protection; eyeglasses with plastic lenses provide virtually no protection.

Additional measures that are helpful to reduce the overall amount of radiation exposure to both the patient and the staff include

1. Intermittent use of the fluoroscopy with reduction in fluoroscopic frame rate to the minimum needed for visualization of pertinent catheter course and cardiac structures
2. Careful attention to catheter pressure tracings by the operator in order to correlate with catheter course on fluoroscopy
3. Use of biplane fluoroscopy only when necessary
4. Cineangiography for recording essential information, with the use of either cineangiography at a lower frame rate or a "store fluoroscopy" capability for less important functions, such as recording balloon inflations.
5. The field of interest should be centered in the detector, with appropriate filters, collimators in use, and the detector as close to the patient as possible.
6. Liberal use of lead shields for positioning between the operator's hands and the x-ray beam and for shielding of other cath lab personnel, such as anesthesia at the head of the cath lab table.

Angiography

The importance of good technique when performing angiography cannot be overemphasized. It is critical to assess the status of the patient prior to and during angiography, making sure that the patient is properly positioned on the table and will not move significantly during the injection of contrast. It is preferable to deliver the bolus of contrast within one cardiac cycle, where feasible, in order to provide the opacification needed for detailed angiography. Catheters used for angiography are thin walled and have multiple side

holes to allow rapid delivery of contrast media at relatively high pressures without catheter recoil (Fig. 12.1). If catheter recoil is anticipated, then the rate of contrast injection can be slowed or the rise time to maximum pressure can be increased. Catheter tips should be free within the cardiac chambers or vessels (to prevent staining or injection into tissue), the body or shaft of the catheter should be positioned to support the catheter during injection to prevent excessive recoil, and the catheter should be positioned in or just proximal to the area of interest. When positioned in a ventricle, a balloon-tipped angiographic catheter may cause less ectopy than other catheters.

It is common during interventional procedures to make calibrated measurements of structures that are defined angiographically. During diagnostic studies, vessel size and ventricular function also can be quantitated in order to provide a thorough assessment of anatomy and function. A given catheter's French size (1 Fr = 0.33 mm) may be used as a reference for calibration to determine the x-ray magnification, allowing absolute measurements to be made from the angiogram; however, small errors in measurement may contribute to larger calibration errors since many structures being measured in the congenital patient are larger than the catheter itself. More accurate measurements may be obtained using a marker catheter, which has radio-opaque bands placed 1 or 2 cm apart (compared with a catheter that may be only 1 to 3 mm in diameter), but the x-ray beam must be perpendicular to the catheter to avoid foreshortening, which causes a calibration error. The most accurate method of calibration is that which is built into the imaging system itself, with the patient positioned at isocenter on the table, whereby automated calibration references allow for measurement of structures or vessels from stored fluoroscopic or angiographic images.

Imaging of the Biventricular Heart

Position of the Camera, Image Intensifier/Detector, and Radiographic Source

Camera angles refer specifically to the angles of the flat panel detectors with respect to the table or patient's chest. As viewed from the flat panel detector, the image plane is perpendicular to a line drawn between the x-ray tube and the detector. For example, in a straight frontal view, the frontal plane detector is positioned at 0 degree and the lateral detector is positioned at 90 degrees for the corresponding orthogonal view. These systems allow independent positioning of the tubes; however, a 90-degree relationship between the two detectors is most often maintained so as to provide corresponding orthogonal views of complex congenital structures.

The importance of angled views for imaging congenital heart lesions was first described by Taussig in the 1940s (31). Subsequently, several manuscripts have described the use of angled views (axial angiography) in the cardiac cath lab (28). While increasingly complicated surgical and transcatheter interventional techniques require more sophisticated angled views and camera adjustment, certain standard angles may be used for common lesions and traditional structural orientation. Again, familiarity with the anatomy and structures that need to be defined during angiographic assessment is required, so that adjustments in camera angles can be made to optimize structural definition. Understanding the views needed and planning ahead may reduce overall radiation exposure (29). An exhaustive discussion of the use of angled views in congenital heart disease is beyond the scope of this chapter; however, basic imaging of the biventricular heart and of several other common defects is discussed below.

Figure 12.7. Infant with tetralogy of Fallot. **A:** Straight AP frontal plane view of right ventricular injection shows the infundibular stenosis and thickened pulmonary valve leaflets (*arrow*), in addition to the pulmonary artery bifurcation. **B:** 90-degree straight lateral projection again shows right ventricle well in addition to the right-to-left shunt through the VSD (*) with filling of the left ventricle (LV).

Right Ventricle and Pulmonary Arteries. The right ventricle is most often imaged in the frontal and straight lateral views (Fig. 12.7). Occasionally, 0 to 25 degrees of cranial angulation is added to the frontal plane detector to provide better definition of the outflow tract. Note the following:

1. Neither view displays the interventricular septum well as the normal right ventricle wraps around the left ventricle. The interventricular septum should be imaged from a left ventricular injection (unless there is simple transposition of the great arteries).
2. The right ventricular outflow tract and main pulmonary artery (MPA) take a posterior course from the heart. Without cranial angulation, there may be overlay of structures (Fig. 12.8); this is most accentuated when the MPA is dilated. The straight 90-degree lateral view displays the infundibulum (Fig. 12.8) and the pulmonary valve well in almost all patients.
3. The right pulmonary artery (RPA) courses posterior to the ascending aorta and travels laterally into the right chest, alongside of and anterior to the right bronchus. It is well seen in the frontal view and almost completely foreshortened in the lateral view. For example, maintaining the detectors at a 90-degree relationship, if the catheter in the RPA is fully foreshortened in the lateral view (adjusted LAO so one is looking “down the barrel” of the catheter), then one can be assured that the frontal plane view (simultaneously adjusted with right anterior oblique [RAO] angulation) will fully display the length of the vessel for accurate measurement.
4. The left pulmonary artery (LPA) courses posteriorly in the chest, anterior to the descending aorta, over and behind the left bronchus. Its most proximal portion may not be well seen in the frontal plane but is better visualized in the lateral view, sometimes with LAO angulation to prevent foreshortening (similar, but “opposite,” to the technique to visualize the RPA). The distal portion of the LPA can be

seen well in a straight lateral view but is foreshortened in the frontal view.

Left Ventricle and Aorta. The left ventricle is imaged using RAO and left anterior oblique (LAO) with cranial angulation (Fig. 12.9A). For an RAO view, the frontal image intensifier has 20 to 30 degrees of straight rightward angulation, whereas the lateral image intensifier has 60 to 70 degrees of leftward angulation with 20 to 30 degrees of cranial angulation. Images created with these projections are shown in Figure 12.9B–F. Note the following:

1. The RAO view displays the anterior portion of the interventricular septum (between the arrowheads in Fig. 12.9B). An anterior muscular ventricular septal defect or a defect arising from conal septal hypoplasia would be displayed in this view as a jet of contrast coursing superiorly into the right ventricular outflow tract. The mitral valve is visualized, and mitral insufficiency (if present) would be noted.
2. The LAO/cranial view displays the membranous, midmuscular, and apical portions of the ventricular septum (Fig. 12.9D). A qualitative assessment of left ventricular function can be performed in this view, and when calibrated systems are in place, the ventricle can be measured in diastole and systole to provide ejection fraction and volumes.
3. Neither view optimally profiles the inlet portion of the ventricular septum.
4. The right coronary artery can be seen in both the RAO and LAO/cranial views, outlining the position of the tricuspid valve. The left main coronary artery is seen in the LAO/cranial view coursing posteriorly from the aortic root, bifurcating into the left anterior descending branch anteriorly and the circumflex branch posteriorly.
5. The aortic valve is imaged well from a left ventricular injection, and the leaflets should be thin and barely visible when normal (Fig. 12.9E,F).

Figure 12.8. Right ventricular (RV) angiogram in an infant with severe pulmonary valve stenosis. In the frontal projection (A), the right pulmonary artery (RPA) is seen well, but the left, which courses posteriorly, is foreshortened. Note the hinge points (*arrows*) of the thickened pulmonary valve that domes in systole and the narrow jet of contrast passing through the valve. The lateral projection (B) displays the thickened, doming pulmonary valve (*arrows*). Most of the left pulmonary artery (LPA) is seen well in this view, but the right pulmonary artery is more foreshortened. There is a prominent ductus diverticulum (*double arrow*). C,D: RV angiogram in an older child with long-standing pulmonary stenosis following balloon valvuloplasty. Frontal plane view (C) shows very dynamic infundibular stenosis (*arrows*) with hyperdynamic RV function and prominent trabeculations. Lateral view demonstrates the dynamic infundibular narrowing well (*arrows*). In both views, there is significant poststenotic dilation of the main pulmonary artery.

For atrioventricular septal defects (which are not commonly seen in the cath lab for purposes of diagnostic angiography but for determination of pulmonary resistance in the older patient) and posterior muscular ventricular septal defects, visualization of the inlet portion of the ventricular septum is required. This requires

more cranial and more vertical angulation than the usual LAO/cranial view and is best displayed in the hepatoclavicular view (Fig. 12.10). For this, the lateral detector is moved to 40 degrees of leftward angulation and 40 degrees of cranial angulation, whereas the frontal camera has 30 degrees of rightward angulation.

Figure 12.9. A: Biplane cardiac cath lab with the c-arms positioned for right anterior oblique (RAO) and long axial oblique projections. The frontal flat panel detector has 20 degrees of rightward angulation, while the lateral flat panel detector has 70 degrees of leftward and 25 degrees of cranial angulation. B: Retrograde left ventriculogram, RAO projection. The anterior muscular septum is indicated by the two *arrowheads*; a ventricular septal defect in this region would appear as a superiorly directed contrast jet. The mitral valve is indicated by the *open arrow*, and mitral insufficiency (if present) would be seen in this view. C,D: Retrograde left ventriculogram in a child with tricuspid atresia, normally related great arteries and a restrictive muscular ventricular septal defect (VSD). Frontal plane (C) with 27 degrees RAO angulation shows contrast appearing in the pulmonary artery (PA), but the ventricular septum is not profiled well from this angle. The corresponding LAO view (D; 61 degrees LAO, 19 degrees cranial) profiles the ventricular septum well and shows both the midmuscular VSD (*arrows*) and the tiny apical trabecular VSDs (*) in addition to the hypoplastic right ventricular chamber (RV).

Figure 12.9. (Continued) E,F: Retrograde LV injection in an infant with a complex vascular ring shows thin aortic valve leaflet in the RAO projection (E) with competent mitral valve (*three arrows*). LAO projection (F) shows the intact ventricular septum very well; the right coronary (*arrowheads*) courses anterior to the right ventricle (which is not opacified in this patient with intact septum).

Figure 12.10. Hepatoclavicular view. A: Left ventriculogram in a child with a complete atrioventricular septal defect. The left ventricle is densely opacified, and contrast has crossed a large ventricular septal defect to outline the common atrioventricular valve (as negative contrast or dark appearance). The right ventricle is not yet fully opacified in this frame. B: Left ventriculogram in a child with tricuspid atresia. The large ventricular septal defect and moderately hypoplastic right ventricle are well seen.

Figure 12.11. Straight AP (A) and lateral (B) views of a right ventricular injection in a patient with d-transposition of the great arteries, ventricular septal defect, and complex upstairs–downstairs ventricular arrangement. Both great arteries fill from the RV injection, although the aorta is more densely opacified and appears directly in front of the pulmonary artery in the frontal plane (A). In the straight lateral plane (B), it is now possible to appreciate the direct anterior (aorta, Ao)/posterior (pulmonary artery, PA) relationship of the great vessels more easily than in a complex angled view. Using such views will aid surgical planning when reoperation is necessary, so that the surgeon may appreciate the relationship of the great vessels to the sternum.

Specific Techniques

Aorta and Pulmonary Arteries

In more complex arrangements of the great vessels, it is often preferred to perform angiography in straight PA and lateral planes in order to define the left–right relationship of the vessels as defined in the frontal plane and, correspondingly, the anterior–posterior relationship in the lateral plane (Fig. 12.11).

Central Pulmonary Arteries

In some patients, particularly those who have tetralogy of Fallot, it is not possible to obtain sufficient cranial angulation to display the pulmonary artery bifurcation in the frontal plane view. Although routine catheterization of infants with tetralogy of Fallot is uncommon, postoperative angiography may be performed if pulmonary branch stenosis is suspected and warrants intervention. The catheter must be positioned beyond the right ventricular outflow tract, as contrast in the right ventricle will obscure the pulmonary arteries. Preferably, RAO and LAO projections, both with cranial angulation, may display the proximal right and left branch pulmonary arteries, respectively. In other cases, where this does not provide adequate visualization of the individual branches, extreme caudal angulation may display the central pulmonary artery bifurcation. Selective pulmonary artery injection will usually be necessary before intervention is undertaken so that detailed anatomy and calibrated measurements can be accurately obtained (Fig. 12.12A,B). In the case of very severe branch stenosis, balloon occlusion angiography with the catheter positioned in the contralateral PA may be used to fill the stenotic vessel (Fig. 12.12C,D).

Left SVC or Venous Collateral Vessels. Definition of the venous drainage of the upper body is necessary prior to a cavopulmonary anastomosis. An angiogram in the left innominate vein will display a left SVC or venous collateral vessels, if they are present. The angiogram may be performed using either a side-hole angiographic catheter positioned at the junction of the left IJ and subclavian veins or with an end-hole catheter using a balloon-occlusion technique. The balloon catheter is positioned in the innominate vein just medial to the left jugular vein, the balloon is inflated (occluding the innominate vein), 2 to 5 mL of contrast is hand injected, and then the balloon is deflated, allowing the contrast to drain via the right SVC into the heart (Fig. 12.13).

Pulmonary Angiography through a Sano, Modified Blalock-Thomas-Taussig Shunt, or Cavopulmonary Anastomosis

Current Norwood stage I palliation for hypoplastic left heart syndrome is carried out with either a Sano modification or a modified Blalock-Thomas-Taussig shunt as a source for pulmonary blood flow. In patients with the Sano modification, a right ventricular injection may show the pulmonary arteries fairly well but the Sano shunt is better visualized in the lateral projection due to overlap of the structures in the frontal plane projection (Fig. 12.14). A modified Blalock-Thomas-Taussig shunt can be easily accessed with a soft-tipped catheter in order to perform an angiogram in the shunt; this provides definition of the shunt caliber and pulmonary artery branch anatomy. With retrograde access, an angled-tip, 0.025 in, hydrophilic wire and a 4 Fr end-hole catheter (such as an internal mammary artery catheter or Judkins right) facilitates this procedure and minimizes negative hemodynamic effects. It is possible to directly measure pulmonary artery pressure if the catheter can be advanced through the shunt without hemodynamic

Figure 12.12. Examples of pulmonary artery branch stenosis. **A, B:** Selective left pulmonary artery (LPA) injection in a patient with proximal LPA stenosis. With the frontal plane detector angled at 16 degrees cranial/6 RAO, the proximal LPA stenosis (*arrow*) is completely foreshortened (**A**). This assures the operator that the orthogonal view (**B**) fully depicts the stenosis (*arrows*) and that measurement of this segment will be accurate. **C, D:** Severe right pulmonary artery (RPA) stenosis in a patient who had repair of anomalous left coronary originating from the mid-RPA. Balloon occlusion is performed with the angiographic catheter in the proximal LPA to occlude flow distally (**C**, *open arrows*), forcing contrast into the tightly stenotic RPA (*arrowheads*). Note the reduced perfusion of the RPA branches, which appear fully distributed (**D**), and is better seen on the corresponding AP view).

embarrassment, and the tip is free without pressure dampening. A selective pulmonary artery injection can also be performed by hand. Additional hand injections can be performed in the shunt with this catheter in order to demonstrate the anatomy more specifically (Fig. 12.14D). In some cases, the pulmonary arteries may be imaged without crossing the shunt, particularly if the patient has low saturations (unless intervention

is anticipated). A balloon-tipped angiographic catheter can be advanced antegrade through the heart into the subclavian artery, distal to the origin of the shunt. The balloon is inflated, occluding the distal subclavian artery, while a power injection of 0.5 to 1 mL/kg of contrast is performed. Positioning the side holes directly over the shunt origin prevents dense filling of the aorta, which would obscure the pulmonary arteries.

Figure 12.13. A,B: Balloon occlusion hand injection of contrast in the innominate vein fills a diminutive left superior vena cava (SVC) that drains to the coronary sinus. Lateral view (B) demonstrates posterior course of the left SVC to coronary sinus.

Figure 12.14. A,B: Right ventricular angiography in an infant with hypoplastic left heart syndrome, following Norwood Stage I with Sano modification (right ventricle to pulmonary artery conduit). A: In the straight frontal plane view, the Sano shunt (*arrows*) lies directly in front of the descending aorta, making it very difficult to see if there is stenosis in the Sano shunt. B: Lateral view nicely demonstrates the position of the Sano shunt (*arrows*) without evidence of stenosis in the Sano conduit itself (prominent right ventricular muscle bundles are present at origin). This view also shows the entire neo-aortic arch very well.

Figure 12.14. (Continued) C: More selective catheter injection in the proximal Sano shunt fills the pulmonary arteries well. D: Retrograde end-hole catheter injection by hand into the mid-portion of a Modified Blalock-Taussig shunt shows typical stenosis (*double arrow*) in the right pulmonary artery immediately adjacent to the shunt insertion; pulmonary arteries are well distributed.

For patients who have advanced through stage II palliation, usually a conversion to bidirectional cavopulmonary anastomosis, IJ access is needed and the pulmonary angiogram is performed with the angiographic catheter positioned in the distal SVC (Fig 12.15).

Pulmonary Vein Wedge Angiography

When the pulmonary arteries cannot be imaged by direct injection or by injection of an aortopulmonary shunt or aortopulmonary collateral, pulmonary vein wedge angiography

Figure 12.15. A,B: Injection via the angiographic catheter positioned in the distal superior vena cava to pulmonary artery anastomosis shows normal-size and normally distributed pulmonary arteries. MPA, main pulmonary artery; RPA, right pulmonary artery; LPA, left pulmonary artery.

Figure 12.16. Pulmonary vein wedge injection with the capillary bed filling retrograde into a very diminutive left upper lobe artery (*arrow*) in a patient with complex pulmonary atresia/ventricular septal defect.

may be necessary (32). An end-hole catheter is advanced antegrade into the pulmonary vein, typically through the patent foramen or atrial septal defect. With free flow of blood upon drawing back on the syringe, a 5- to 12-mL syringe containing 1 to 4 mL of contrast (0.3 mL/kg, maximum 4 mL) is held in vertical position and a small amount of blood is drawn into the syringe. The contrast forms a separate layer in the syringe below the blood and the pulmonary vein is occluded by advancing the catheter. The contrast and saline are slowly hand injected to backfill the pulmonary capillary bed and pulmonary artery (Fig. 12.16), continuously watching the

appearance of the vascular bed on the monitor. If the contrast is injected too rapidly, the capillaries may rupture into the airways, causing coughing and respiratory distress. On the other hand, if there is significant flow to that pulmonary artery from an aortopulmonary collateral vessel, visualization by a hand injection may be difficult and it may be necessary to balloon-occlude the collateral vessel during the vein wedge injection.

Selective Coronary Arteriography

In some pediatric patients, adequate imaging of the coronary arteries is achieved with an aortic root injection, or even a left ventriculogram. Indications for selective coronary angiography include a coronary artery fistula (including pulmonary atresia with intact ventricular septum), Kawasaki disease, heart transplant, and coronary ischemia (Fig. 12.17). Coronary catheter size refers to the diameter of curvature of its preformed distal end: a Judkins Left or JL-2 catheter is preformed to access the left coronary artery with a 2-cm diameter of curvature of the distal tip. The proper size catheter is a function of the aortic root diameter. Some pediatric patients who require selective coronary angiography (e.g., previous arterial switch procedure, heart transplant) have atypical locations of the coronary artery origins. Successful cannulation of the coronary arteries requires an understanding of the anatomy and choosing the appropriate catheter for this anatomy; often an aortic root injection will provide a good road map if there is difficulty with selective cannulation. When the aorta arises from the right ventricle (transposition of the great arteries), antegrade selective coronary angiography can be performed, but the retrograde approach is still preferred.

Definition of Aortopulmonary Collateral Vessels

In patients with obstructed pulmonary flow (tetralogy of Fallot, pulmonary atresia, complex single ventricle), accurate definition of the collateral supply to the pulmonary arteries is crucial prior to surgical or transcatheter intervention. Initially, an aortogram is performed to display all aortopulmonary collateral vessels. In an infant, this may be accomplished

Figure 12.17. Selective coronary artery angiography in a patient with history of infantile Kawasaki disease and giant coronary aneurysms seen on echocardiography. A,B: Right coronary injection shows two large aneurysms (*arrow*).

Figure 12.17. (Continued) C,D: Left coronary injection shows large proximal aneurysm in the left anterior descending branch (double arrow) with more distal smaller aneurysm (arrowhead); there is a small saccular aneurysm in the circumflex artery (arrow).

by an antegrade angiography (Fig. 12.18A), balloon-occlusion injection in the descending aorta (Fig. 12.18B), or with a retrograde aortic angiogram (Fig. 12.18C). Once the collateral vessels are identified, individual selective hand injections are typically performed in each of the collaterals, defining the

pulmonary segments supplied by the collateral and whether there is communication with the “true” pulmonary arteries (Fig. 12.18D). Aortopulmonary collateral or dilated bronchial vessels can occur in patients with transposition of the great arteries, although in most cases, they are of no physiologic

Figure 12.18. A: Antegrade angiography with catheter advanced from right ventricle into ascending aorta in an infant with tetralogy of Fallot/pulmonary atresia and a large tortuous patent ductus arteriosus supplying diminutive but confluent pulmonary arteries (subsequent angios, not shown, did not demonstrate collaterals). B: Balloon occlusion aortogram in an infant with very complex pulmonary atresia/intact ventricular septum/Alagille syndrome. Injection is performed with the catheter-advanced antegrade through the atrial septal defect, left ventricle, and aortic valve, with the catheter positioned just above the diaphragm. The balloon is inflated so that contrast fills the proximal descending aorta outlining the very complex collateral supply.

Figure 12.18. (Continued) C: Retrograde aortogram in complex pulmonary atresia/VSD provides a “road map” of the collateral vessels before selective angiography is undertaken. D: Selective hand injection with an end-hole catheter fills the true pulmonary artery confluence in this same patient (as in panel C).

significance; a descending aortogram should identify these vessels, which can then be selectively injected and potentially coiled if hemodynamically important (33).

Complications

Although patients referred for cardiac catheterization are now smaller and have more complex cardiac abnormalities, the procedure has become safer. Complication rates are higher for interventional procedures than diagnostic procedures and are more frequent in neonates and infants than older patients. The most common complication is related to vascular access (34). Mortality rates, currently reported at approximately 0.25% to 0.29%, are usually related to the severity of illness in this population (34,35).

Arrhythmias

Arrhythmias during cardiac catheterization are common and are usually related to catheter contact with the atrial wall or ventricular myocardium. Such benign arrhythmias resolve with catheter repositioning. Careful catheter manipulation and, in some lesions, using tip-deflector wires or balloon-tipped catheters to diminish irritation of the myocardium are helpful in avoiding arrhythmias. Catheter-induced atrioventricular block can easily occur in children with atrioventricular discordance (S, L, L), but can also occur in children with D-transposition of the great arteries (S, D, D) and tetralogy of Fallot, particularly during passage of a catheter from the right ventricle to the aorta. Atrioventricular block generally resolves spontaneously, but if prolonged or associated with hemodynamic compromise, temporary transvenous pacing may be necessary (34).

Hypoventilation

The combination of pharmacologic sedation and physical immobilization during cardiac catheterization may foster hypoventilation. In the current era, approximately

three-fourths of congenital cardiac catheterizations will be performed with general anesthesia, which minimizes these risks (35). Continuous pulse oximetry saturation monitoring, end-tidal CO₂ monitoring (in intubated patients), and arterial blood gas sampling all aid in assuring maintenance of stable airway status during the procedure. The position of the endotracheal tube should be checked during initial fluoroscopy. Regardless of whether conscious sedation or general anesthesia is utilized, careful attention to airway management is required in all cases.

Embolism

Although pulmonary or systemic emboli are rare during cardiac catheterization in children, the potential for an embolic event is real, and the results can be devastating. Air, thrombus, broken wires, or catheters all can embolize. Conditions that increase the risk of an embolic event include the use of large sheath size (particularly when placed in the left heart or with a right-to-left shunt), cyanosis with erythrocytosis or anemia, and prolonged catheter manipulation in the ascending aorta or transverse arch. Precautions that decrease the risk of an embolism include systemic heparinization (50 to 100 U/kg as an initial bolus dose with appropriate monitoring of the activated clotting time according to locally available assays), frequent aspiration and flushing of catheters, use of carbon dioxide to inflate balloon catheters, and positioning the arterial catheter distal to the brachiocephalic vessels.

Cardiac Perforation

Improved catheter technology and better noninvasive definition of the cardiac anatomy have resulted in fewer complications, including cardiac perforation. The most common sites of cardiac perforation are the atrial appendages (especially if the heart is viewed in only one plane), the right ventricular outflow tract of small infants, the right ventricle during endomyocardial biopsy (particularly in smaller children with myocarditis), the left ventricular apex, and the aortic valve cusps.

Pushing a wire or Brockenbrough needle through the wall of the heart usually does not cause a problem as the puncture site is very small; however, passage of anything larger (e.g., dilator, catheter, sheath) through the atrial wall is likely to require surgical repair. Perforations in the ventricle are more likely to seal over without needing surgery.

When hypotension occurs during or shortly after cardiac catheterization, cardiac perforation resulting in tamponade must be considered. An echocardiogram should be obtained immediately. Fluoroscopically, there are two clues to alert the staff about a pericardial effusion: an enlarged cardiac silhouette with absent movement of the cardiac silhouette. Therefore, it is important to know the cardiac size, shape, and motion prior to starting the catheterization. When cardiac perforation occurs, initial treatment includes removal of the catheter and observation. Any coagulopathy should be corrected. If clinically indicated, pericardiocentesis is performed and a pericardial drain (pigtail catheter) is placed. By connecting a stopcock and sterile IV tubing to the pericardial drain, the blood can be reinfused into a venous catheter to aid in maintaining hemodynamic stability while monitoring the rate of persistent bleeding closely. If there is continued accumulation of pericardial blood, surgical repair should be immediately arranged.

Hypercyanotic Episode

Despite appropriate precautions (hydration, sedation, careful catheter manipulation), infants and children with tetralogy of Fallot and some forms of double-outlet single ventricle with infundibular pulmonary stenosis are at risk for a hypercyanotic episode ("tet spell") during or shortly after cardiac catheterization. This complication occurs more frequently in small, cyanotic infants. Often, thorough echocardiographic assessment will have determined much of the anatomy, leaving one or more specific remaining questions to be expeditiously answered during catheterization (e.g., coronary artery anatomy, distal pulmonary artery anatomy, additional ventricular septal defects, and collateral vessels). If possible, avoiding deliberate catheter manipulation across the tightly stenotic pulmonary outflow tract may lessen catheter-induced hypoxemia. Increasing cyanosis, fluctuating arterial oxygen saturations, metabolic acidosis, all can be indications of an impending hypercyanotic episode. Appropriate treatment includes administration of volume (saline, or red blood cells if very anemic), IV phenylephrine or other peripheral vasoconstrictors, sodium bicarbonate (for acidosis), and intubation (if not already performed). General anesthesia can be helpful but may not "break" a hypercyanotic episode in a patient who was consciously sedated for the procedure.

Patient with Pulmonary Vascular Disease

It has been long documented that there is an increased risk associated with cardiac catheterization in patients with markedly elevated pulmonary vascular resistance (36). The periprocedural mortality has been reduced significantly by advances in airway management, sedation, and pharmacologic management of pulmonary hypertension, in addition to a safe procedure carried out by a team of experienced pediatric cardiologists and cardiac anesthesiologists. Indications for catheterization include baseline hemodynamic evaluation, assessment of pulmonary reactivity using pharmacologic agents, and uncommonly, potential for intervention to create an atrial septal defect. In most cases, pulmonary artery angiography should be avoided, as it could precipitate acute, sometimes fatal, pulmonary artery vasoconstriction.

Peripheral Vascular Injury

Vascular complications are among the most common complications following congenital cardiac catheterization (34). Factors contributing to peripheral vascular injury include small vessel size (in infants), large catheter or sheath size, multiple previous entries into the vessel, multiple catheter exchanges, and improper technique for achieving vascular access or hemostasis. Measures that reduce the incidence and severity of peripheral vascular injury should include attention to the following: skilled percutaneous access, use of ultrasound to visualize the vascular structures, use of finely tapered sheaths and dilators over appropriate-sized wires, systemic heparinization, and efficient execution of the procedure minimizing the time catheters are in the vessel (37). At the end of the procedure, the catheters and sheaths should be aspirated to remove any thrombus and then removed, allowing the vessel to bleed back briefly. Hemostasis is achieved by applying pressure with one or two fingers cephalad to the site of percutaneous entry, which should be at the site of entry into the vessel. Routine use of sandbags or mechanical devices to apply pressure to percutaneous sites is contraindicated in pediatric catheterization procedures.

After a diagnostic catheterization, pulse loss is rare. Even in small infants, the use of a 3 Fr pigtail catheter tapered to a 0.021-in wire should allow a safe retrograde arterial catheterization (although the catheter flow rate is low). When loss of a pulse occurs, heparin is continuously infused until the pulse returns or for 12 to 24 hours. There is likely a component of arterial spasm, and heparin may prevent thrombus formation at the site of spasm. If the pulse does not return, treatment with a thrombolytic agent may be instituted unless contraindications are present (38,39).

Latex Allergy

Latex allergy can result in a wide range of symptoms, from contact urticaria to life-threatening anaphylaxis. Overwhelming anaphylaxis generally occurs during surgery and results from patient exposure to surgical latex gloves. This problem has occurred in patients who previously had minor symptoms caused by contact with latex (38). However, there have been no reports of anaphylaxis from the use of intravascular latex catheter balloons. For any patient with any history of latex allergy undergoing cardiac catheterization, standard institutional protocols for latex precautions should be observed.

ACKNOWLEDGMENT

The authors wish to acknowledge previous authors of this chapter, Drs. Ronald G. Grifka, Nancy D. Bridges, Michael P. Freed, Martin P. O'Laughlin, and Charles E. Mullins. Many of their initial contributions remain as core information in this chapter.

Ralf J. Holzer ■ John P. Cheatham

Catheter-based techniques, whether palliative or corrective, are now the accepted therapy for many congenital cardiac defects. Interventional or, better termed, therapeutic catheterizations were initiated by Dotter and Judkins (1), who first reported the treatment of peripheral vascular lesions during a catheterization in 1964, when they dilated a stenotic peripheral vessel through a cut-down on the vessel. The next major innovative accomplishment and the first intracardiac therapeutic catheterization procedure for pediatric congenital heart disease (CHD) was the balloon atrial septostomy (BAS) done by Rashkind and Miller (2) in 1966. This procedure really “set the stage” for all therapeutic catheterization procedures used today. In 1968, Porstmann et al. (3) reported the first non-surgical corrective procedure in the catheterization laboratory with their description of a technique for closure of a patent ductus. Vascular occlusion coils were introduced by Gianturco et al. (4) in 1975, and in 1976, King et al. (5) were the first to describe the closure of atrial septal defects (ASDs) in the catheterization laboratory. Even though their device has not found widespread use, it set the stage for future development of transcatheter devices. One of the largest contributions to interventional cardiology has probably been made by Gruentzig, a Swiss native who in 1976 reported on dilation of peripheral vessels with noncompliant balloons. This initiated a rapid innovative spurt within the congenital cardiac community during which narrowed lesions at various locations were treated with balloon angioplasty, frequently initially in a noncontrolled fashion. In 1982, Dr. Jean Kan (6) reported the first successful transcatheter static balloon pulmonary valvuloplasty (BPV) and Dr. James Lock et al. (7) in 1988 used the clamshell device to occlude a ventricular septal defect (VSD) using a percutaneous approach. Dr. Charles Mullins introduced endovascular stents into the management of patients with congenital cardiac lesions (8), and the long list of innovations reached another milestone when Dr. Phillip Bonhoeffer et al. (9), a German cardiologist working in France in 2000, performed the first transcatheter pulmonary valve replacement in a human. Transcatheter valve therapies and other interventional therapies to treat patients with structural heart disease have rapidly increased over the past few years. Another milestone was reached when the Melody valve (Medtronic, Minneapolis, MN) gained Food and drug administration (FDA) Humanitarian device exemption (HDE) approval in January 2010. These therapies are not limited anymore to patients with CHD. In fact, transcatheter aortic valve implantations in adults have overtaken transcatheter valve therapies in the congenital population, with several thousands of implantations of the CoreValve (Medtronic, Minneapolis, MN) in adults having been performed thus far.

In this section, the most important therapeutic catheterization procedures performed as of this writing are discussed. This chapter is not intended as a complete and exhaustive textbook of interventional techniques, but instead should give the reader a general overview of therapeutic catheterization.

It should be emphasized that not every pediatric cardiologist, or, for that matter, every center, should offer every therapeutic catheterization procedure. For any procedures to be performed at any particular institution, minimal specific skills are required, special techniques must be mastered and maintained, and a large inventory of specialized and expensive catheters and devices must be stocked to offer the patient an optimal procedure. Absence of appropriate qualifications and equipment can result in unnecessary risk to the patient without a reasonable chance of the therapeutic catheterization procedure being successfully accomplished. In fact, even if the patient is not acutely harmed by the attempt, it is important to be aware of the fact that the next procedure in a more appropriate setting might be compromised by a previously unsuccessful attempt.

We have used and expanded upon this chapter published in other editions of this textbook and therefore acknowledge the previous contributions made by Drs. Nancy Bridges, Martin O’Laughlin, Charles Mullins, and Michael Freed.

ADVERSE EVENTS AND QUALITY IMPROVEMENT

For many years, reporting of procedure-related adverse events was limited mostly to single-center retrospective experiences, often without any clearly and consistently applied criteria of what would be considered an adverse event, and how its severity should be defined (10–12). Over the years, several multi-center registries have captured procedural outcomes including efficacy and occurrence of adverse events, which included the Valvuloplasty and Angioplasty of Congenital Anomalies (VACA) registry, Mid-Atlantic Group of Interventional cardiology (MAGIC), and Congenital Cardiovascular Interventional Study Consortium (CCISC) (13–15). The data derived from these registries often provided the only prospective multicenter outcome data for many types of procedures.

A more systematic capture of procedure-related adverse events was accomplished recently through the Congenital Cardiac Catheterization Project on Outcomes (C3PO) multi-institutional registry (16), using definitions for event severity and preventability as defined in the International Pediatric Congenital Cardiology Code nomenclature (17). This registry documented not insignificant rates of adverse events, 10% for diagnostic cases and 20% for interventional procedures. Higher severity (level 3 to 5) adverse events occurred in 9% of interventional cases and 5% of diagnostic cases.

However, to accurately compare adverse event rates and outcome between institutions and operators, an adjustment for case mix and hemodynamic vulnerability is required. Using consensus-based and empirical methods and methods derived from the C3PO dataset, Bergersen et al. (18) recently reported on

procedure-type risk groups, separating different types of diagnostic and interventional procedures into four different risk groups, ranging from diagnostic procedures performed in patients over 1 year of age (Risk Group 1) to balloon angioplasty of four or more pulmonary artery branches (Risk Group 4).

Following the definition of procedure-type risk groups, Bergersen et al. reported on hemodynamic variables associated with vulnerability for AE, which were determined based on an empirical analysis of the C3PO data set. The combination of variables that were identified to offer the best predictive performance for high severity adverse events included systolic main PA pressure ≥ 45 mm Hg (two-ventricle) or mean PA pressure ≥ 17 mm Hg (single-ventricle), systemic ventricular end-diastolic pressure ≥ 18 mm Hg, mixed venous saturations $< 60\%$ (two-ventricle) or mixed venous saturation $< 50\%$ (single-ventricle), and systemic saturations $< 95\%$ (two-ventricle) or $< 78\%$ (single-ventricle) (19,20).

However, incidence of adverse events and efficacy of an interventional procedure do not exclusively depend on patient-specific characteristics and procedure type. In fact, Holzer et al. (20,21) found that operator experience of < 10 years was an important independent risk factor for procedure-related higher severity adverse events for both pulmonary artery rehabilitation and BPV.

These various quality improvement efforts have culminated in the development of Improving Pediatric and Adult Congenital Treatment Registry and National Cardiovascular Data Registry, which were designed to capture all catheterization procedures performed nationwide within the United States in pediatric and adult patients with CHD. While the registry is only in its first year of data collection, hopefully it will eventually allow operators and institutions to compare performance objectively on a national level (22).

THE INTERVENTIONAL ARMAMENTARIUM

General Considerations

The spectrum of transcatheter procedures available for the treatment of children and adults with CHD has rapidly increased over the last three decades. While the technical skills of the operator combined with a sound anatomic and hemodynamic understanding of a patient's condition remain without a doubt the most important ingredients for the successful outcome of an interventional catheter procedure, the choice of the appropriate equipment is almost equally important for a successful outcome. With rapid progress that is being made in the development of new and more refined equipment, the operator has an inherent responsibility to keep up-to-date with these development efforts and to avoid procedural failures in situations where the use of a different type of equipment may lead to a very different outcome. Even though most interventional meetings center on new device developments, the choice of appropriate balloons, catheters, sheaths, and wires is in many situations even more important for a successful outcome. It is beyond the scope of this discussion to describe all available balloon catheters, but operators have to make a well-informed decision on which balloon to use based on profile, rated maximum pressure, available lengths, and degree of compliance and adjust their choices to suit specifically the therapeutic intervention that is intended. For example, balloon-in-balloon (BIB) catheters (NuMED, Hopkinton, MA) are specifically suited for stent deployment, but the family of high-pressure Mullins balloons (NuMED, Hopkinton, MA) or ultrahigh-pressure Atlas balloons (Bard Peripheral Vascular, Inc., Tempe, AZ) aid exquisitely when high-pressure balloon angioplasty or stent re-expansion to a larger diameter is required.

Even though transcatheter devices have long been available for the management of congenital cardiac lesions, the greatest progress has been made through introduction of a large variety of newer devices that were specifically developed for individual congenital cardiac lesions over the past 10 years. This progress has enabled many procedures to be safely performed in a much wider range of clinical centers. In this chapter, a variety of device-specific sections have been taken with permission from an article on this topic that was published in "Expert Review of Medical Devices" (23).

The following discussion is centered on transcatheter devices that are presently approved or investigated within the United States and includes a discussion of devices available for occlusion of septal defects as well as occlusion of vascular structures. The spectrum of devices that is discussed below is not intended to be complete, but rather represents subjective choices of the authors.

Devices for Occlusion of Septal Defects

The development of transcatheter devices for the occlusion of septal defects has been progressing at a rapidly accelerating pace, ever since King et al. (5) first described a percutaneous technique to close ASDs. Various devices are presently approved by the FDA, either for regular use or under a HDE, while others are presently being evaluated in phase I and II clinical trials. Even though devices are usually developed to address a specific type of septal defect, it is not uncommon that they are also used for occlusion of other types of defects on an "off-label" basis, once regular premarket approval (PMA) has been obtained.

The AMPLATZER Septal Occluder (ASO) gained FDA approval in December 2001 for occlusion of secundum ASDs as well as fenestrations after surgical completion of a Fontan-type circulation. It is presently the most frequently used transcatheter device for occlusion of septal defects within the United States and worldwide. Modifications of the principle device design have since been developed to accommodate the specific requirements of patent foramen ovale (PFO) (AMPLATZER PFO Occluder), multifenestrated ASD (AMPLATZER Cribiform Septal Occluder), muscular VSD (AMPLATZER Muscular VSD Occluder), perimembranous VSD (AMPLATZER Membranous VSD Occluder), and postmyocardial infarction VSD (AMPLATZER Muscular VSD (Postmyocardial Infarction) Occluder), most of which are presently undergoing or have just completed phase I or phase II FDA-sponsored clinical trials. The AMPLATZER Muscular VSD Occluder is approved for use in "high-risk" muscular VSDs. Figure 13.1 shows the family of AMPLATZER devices. (All of these devices are manufactured by AGA Medical Corporation, Golden Valley, MN.)

The CardioSEAL ASD occlusion device (Nitinol Medical Technologies, Boston, MA) was developed as a successor to the Clamshell device. At the same time as the ASO was approved, the CardioSEAL device gained regular use approval by the FDA for occlusion of "high-risk" muscular VSDs, under a registry requirement. Furthermore, it gained HDE approval for occlusion of PFO in patients with associated recurrent stroke who were taking therapeutic Warfarin. A self-centering modification of the CardioSEAL device, the STARFlex Occluder had been evaluated for the treatment of PFO and stroke (CLOSURE I) but is no longer marketed (24,25).

Another device that has recently acquired FDA PMA for the occlusion of ASD is the HELEX Septal Occluder (W.L. Gore & Associates, Flagstaff, AZ) (26). A variety of other devices have been used outside the United States but have not gained FDA approval (27–30).

Figure 13.1. AMPLATZER Devices. (A) AMPLATZER Septal Occluder, (B) AMPLATZER PFO Occluder, (C) AMPLATZER Muscular VSD Occluder, (D) AMPLATZER Membranous VSD Occluder, (E) AMPLATZER Duct Occluder, and (F) AMPLATZER Vascular Plug. The images were provided by AGA Medical Corporation, Golden Valley, MN.

AMPLATZER Septal Occluder

The ASO, first described in 1997, is a double-disc device formed of 0.005-inch Nitinol mesh (31,32). It consists of two discs that are linked to each other through a central connecting waist. Dacron fabric is incorporated into each disc as well as the connecting waist to enhance thrombosis. The device size is defined by the diameter of the connecting waist and is available in sizes from 4 to 38 mm. A 40-mm device is available outside the United States. The connecting waist has a length between 3 and 4 mm with the diameter of the left atrial disc exceeding the connecting waist by 12 to 16 mm, while the diameter of the right atrial disc exceeds the connecting waist by 8 to 10 mm.

AMPLATZER Cribriform Septal Occluder

A device that is less frequently used, the AMPLATZER Cribriform Septal Occluder, has very specific characteristics that make it an excellent choice for closing multifenestrated ASDs. The device was introduced in 2003 and has recently gained FDA PMA after completing phase II clinical US trials (33). Its design resembles the AMPLATZER PFO Occluder, with the notable exception of both discs being equally sized. It is available in sizes of 18, 25, and 35 mm diameter. The thin central connecting waist allows a much larger area of the device to be available to cover the atrial septum when compared to the ASO, while at the same time avoiding any septal distortion through the central connecting waist. This not only makes it an excellent choice for multifenestrated ASDs but it also allows stabilization of an associated aneurysmal atrial septum. However, placement of the device through the most central defect is important and therefore high-quality transesophageal

echocardiography (TEE) or intracardiac echocardiography (ICE) guidance is imperative to achieve the desired result.

AMPLATZER PFO Occluder

The design of the AMPLATZER PFO Occluder, albeit similar to the ASO, accommodates very specific morphological characteristics of the PFO. Similar to the ASO, the PFO Occluder is a double-disc device formed of 0.005-inch (18- and 25-mm device) or 0.006-inch (35-mm device) Nitinol wire mesh. However, it is non-self-centering and consists of two discs that are linked to each other through a central connecting waist, with Dacron fabric being incorporated into each disc. The connecting waist is thin with a length of 3 mm, thereby accommodating the tunnel-type morphology of a PFO without distorting the atrial septal anatomy. In contrast to the ASO, the right atrial disc is equal or larger in size than the left atrial disc. The device is available in three size configurations of right and left atrial disc: 18/18 mm (18-mm device) (34), 25/18 mm (25-mm device), and 35/25 mm (35-mm device). The relatively large size of the discs in relation to the connecting waist makes this device particularly useful to flatten any coexisting atrial septal aneurysm. Its clinical use was first described in 2000 by Waight et al. (35). The device has investigational device exemption approval and is being evaluated in the RESPECT trial.

AMPLATZER Muscular VSD Occluder

The AMPLATZER Muscular VSD Occluder was added to the interventional armamentarium in 1999 (36,37). Similar to most AMPLATZER devices, it is a double-disc device made of 0.0005-inch Nitinol mesh wire. Both discs are equal in size and exceed the diameter of the central connecting waist by

8 mm. Dacron fabric is incorporated into both discs as well as the central connecting waist, which has a length of 7 mm to accommodate the increased septal thickness of muscular VSD. This determines the size of the device, which is available from 4 to 18 mm.

AMPLATZER Muscular VSD (Postmyocardial Infarction) Occluder

The AMPLATZER Muscular VSD (Postmyocardial Infarction) Occluder was first described in 2003 in a small series by Goldstein et al. (38). It was developed as a modification of the AMPLATZER Muscular VSD Occluder to take account of the increased septal thickness in adults. It is a double-disc device made of 0.0005-inch Nitinol mesh wire. The discs are symmetrical and slightly larger than those of the muscular VSD device and exceed the connecting waist by 10 mm. The length of the central connecting waist is 10 mm, which is longer than the waist of the muscular VSD Occluder. The device is available in sizes from 16 to 24 mm. Similar to the muscular VSD device, Dacron fabric is incorporated into both discs and the central connecting waist.

AMPLATZER Membranous VSD Occluder

The inherent morphological and anatomical characteristics of perimembranous VSD in the past have resulted in suboptimal outcomes of attempts at percutaneous device closure (39). The AMPLATZER Membranous VSD Occluder is the first device that has been specifically designed for occlusion of these defects. It was first described in a natural swine model in 2000 with Hijazi et al. (41) reporting the first clinical experience in 2002 (40).

In contrast to other AMPLATZER devices, the Membranous VSD Occluder is an asymmetrical double-disc device made of 0.004-inch Nitinol wire mesh. The asymmetrical left-ventricular disc exceeds the central connecting waist at the superior, aortic end by just 0.5 mm and at the inferior, apical end by about 5.5 mm. A platinum marker is incorporated into the apical end of the left ventricular (LV) disc to aid device positioning. In contrast, the right ventricular (RV) disc is symmetrical in relation to the connecting waist and exceeds its diameter by a total of 4 mm. The connecting waist has a length of just 1.5 mm and the device is available with the diameter of the connecting waist ranging from 4 to 18 mm.

HELEX Septal Occluder

The HELEX Septal Occluder was first described by Zahn et al. (26) in 2001. Its frame is made of a long Nitinol wire, with a strip of polytetrafluoroethylene (PTFE) fabric attached alongside. Three “eyelets” are embedded along the device to facilitate accurate positioning, one at each end and one in central position between both discs. In its deployed status, the device forms two circular discs that are composed by the spiraling Nitinol wire with its attached PTFE membrane. The device is available in sizes from 15 to 35 mm (diameter of discs) in 5-mm increments with a device to defect ratio of 1.7 to 2:1 being recommended. When compared to the ASO, this device has a lower profile and a more atraumatic contour. It is delivered through a 9 Fr catheter, rather than relying on a long sheath. Its also creates less distortion of the atrial septum prior to its release.

Devices for Occlusion of Vascular Structures

Porstmann et al. (3) introduced a technique of transcatheter closure of the ductus arteriosus in 1968. The procedure was complicated and required a large arterial cannulation and as a result, this technique never found widespread use.

Rashkind and Cuaso, while still working on the septostomy balloon, also developed a device for closure of the patent ductus. This device was a small umbrella that attached to the ductus by tiny hooks at the ends of the umbrella arms. The first successful use of this early device was reported in 1979 (42). It was modified into a double umbrella that is fixed in the ductus by a spring mechanism of the arms expanding against the vessel walls. Even though the device had undergone extensive trials, resulting in more than 700 prospectively monitored patent ductus arteriosus (PDA) occlusion procedures performed in the United States, it never quite made it to regular use approval (43,44). However, the extensive experience gained in this process formed the basis upon which virtually all subsequent devices have been developed.

A large variety of devices have been developed to facilitate occlusion of vascular structures. Embolization coils have been used by general interventional radiologists for almost three decades (4). However, it was not until the 1980s that these were introduced into the interventional armamentarium of the pediatric cardiologist, initially for occlusion of abnormal collateral vessels (45) and subsequently in 1992 for the occlusion of patent arterial ducts in children (46). Gianturco coils are available in a variety of sizes but the lack of a controlled release mechanism ultimately stimulated the development of Jackson coils, which are presently only available outside the United States (47), and its US counterpart, the Flipper coil (Cook, Bloomington, IN). An MRI compatible modification of the Gianturco and Flipper coil, the MRye coil (Cook, Bloomington, IN) was introduced in 2006 and has since evolved as the most commonly used coil to date, mainly due to the notably lower incidence of MRI artifact (48).

Even though coils were and still are used “off-label” for the occlusion of the patent arterial duct, it was not until 2003 that a custom-made device designed specifically for the occlusion of the PDA gained FDA PMA (49). The AMPLATZER Duct Occluder (ADO) (AGA Medical Corporation, Golden Valley, MN), which was first introduced into clinical use in 1997, has since remained the only device approved specifically for this indication (49). However, a modification of the device, the ADO II (AGA Medical Corporation, Golden Valley, MN) is presently undergoing phase II clinical trials in the United States (50–52). In addition, the Nit-Occlud PDA occlusion device (pfm AG, Cologne, Germany), a modification of the Duct-Occlud device, has undergone phase II clinical trials with promising results (53,54). An additional “coil modification,” the Gianturco-Grifka Vascular Occlusion Device (GGVOD) (Cook, Bloomington, IN) has gained FDA approval, even though its cumbersome delivery technique has prevented its widespread use. A large variety of additional coils is available for regular use, such as Target coils (Target therapeutics, Fremont, CA), Tornado coils (Cook, Bloomington, IN), and Nester coils (Cook, Bloomington, IN). However, these are less frequently used in congenital cardiac interventions and therefore are not discussed further in this chapter.

Further additions to the interventional armamentarium include the AMPLATZER Vascular Plug, which was first described in 2003. It has since acquired regular use approval for peripheral arterial and venous embolizations (55). A modification, the AMPLATZER Vascular Plug II (AGA Medical Corporation, Golden Valley, MN) has since gained PMA approval. Other devices are available internationally, but not approved in the United States.

AMPLATZER Duct Occluder and Duct Occluder II

The ADO was first introduced into clinical use in 1997 (49). It is, at present, the most commonly used device to close medium- or larger-sized PDA. The device is mushroom-shaped and made of 0.005-inch Nitinol wire mesh. The central skirt of the device is cone-shaped with the pulmonary end being

about 1 to 2 mm smaller than the aortic end. A microscrew for attachment of the delivery cable is recessed into the pulmonary end of the device. The device is further expanded at the aortic end through a symmetrical retention disc, in which the diameter exceeds the size of the aortic end of the skirt by about 4 to 6 mm. Dacron fabric is incorporated into the retention disc and the skirt. The size of the device, defined by a combination of the diameters at aortic and pulmonary end of the skirt, is available from 5/4 to 16/14 mm. The total length of the device ranges from 5 to 8 mm.

The ADO II was first described in 2009, and is presently undergoing phase II clinical trials within the United States (50–52). In contrast to the standard Duct Occluder, the ADO II is a double-disc device with a central connecting waist. The connecting waist has a length of either 4 or 6 mm and a diameter between 3 and 6 mm. The two discs exceed the diameter of the connecting waist by 6 mm. The device is made from triple layered mesh of braided 144 Nitinol wire and does not incorporate any polyester fabric. Due to its symmetric shape, it can be delivered antegrade as well as retrograde, using 4 or 5 Fr delivery catheters.

AMPLATZER Vascular Plug and Vascular Plug II

The use of the AMPLATZER Vascular Plug in transcatheter therapy of congenital cardiac lesions was first reported in 2003 (55). The device is cylindrical in shape and formed of 0.0015- to 0.003-inch 144 Nitinol wire mesh. It is available in diameters from 4 to 16 mm in 2-mm increments, with a device length of 7 to 8 mm. In contrast to other AMPLATZER devices, Dacron fabric is not incorporated into the device.

The AMPLATZER Vascular Plug II is a modification of the standard vascular plug, consisting of three segments instead of just one. It is made of a triple layered mesh of braided 144 Nitinol wire and is available in diameters from 3 to 22 mm. The device can be delivered through 5 to 9 Fr Guide catheters. The Plug II has shown excellent occlusive properties, even for higher flow arterial structures that could not be occluded with the standard vascular plug (56,57).

Embolization Coils

Stainless steel coils for embolization of vascular structures have been introduced in the early 1970s (4) and have since undergone few modifications. At present, “Gianturco” embolization coils (Cook, Bloomington, IN) are made of stainless steel spring wire (0.004 to 0.008 inch) with synthetic Dacron fibers being added for increased thrombogenicity. Each extended spring coil has a stiffening “core” wire that facilitates the forming of a coil of variable length and diameter, once the extending forces are removed. The coils are delivered in their extended length, requiring delivery catheters of 0.025, 0.035, 0.038, or 0.052 inch, depending on the size of the spring coil. The coils are available in diameters between 2 and 15 mm and a length that allows formation between 1.1 to 5.3 loops. Even though the 0.035- and 0.038-inch varieties are most frequently used, 0.025- and 0.052-inch coils have maintained their usefulness for very specific occasions. The detachable Flipper coil (Cook, Bloomington, IN) is a variation of the standard 0.035-inch Gianturco coil and includes a controlled release mechanism. It became available in the United States in 2001. However, early versions of this coil lacked thrombogenic Dacron fibers, and the 0.035 coil remains less robust than the 0.038 inch standard Gianturco coil (58). Modifications of the standard Gianturco and the Flipper coils were first described in 2008 (48). These coils include the MRye coil and the MRye Flipper coil (Cook Medical, Bloomington, IN), which are made of MRye super alloy with a very similar design to the standard coils. However, the MRye coil is only available in the 0.035- and 0.038-inch varieties.

Figure 13.2. Nit-Occlud PDA occlusion system. The image shows the aortic spiral disc with the device still attached to the delivery system.

Nit-Occlud

The Nit-Occlud PDA occlusion system, developed as a successor to the Duct-Occlud device, was introduced in 2001. The device is made up of wound 0.01 inch Nitinol wire, which forms a secondary helix-type loop, thereby conforming to a “double opposing cone” shape (Fig. 13.2) (53,54,58). The device has reinforced distal windings at the aortic end that prevent it from pulling through the PDA, while tighter and softer central windings allow the device to conform to the narrow portions of the PDA at the pulmonary end, thereby allowing more efficient occlusion of the duct. No fabric is attached to the device, with occlusion being facilitated through the metal windings alone. The device is available in three principal versions, the Nit-Occlud Flex, the Nit-Occlud Medium, and the Nit-Occlud Stiff, which differ from each other through an increasing stiffness. The devices are available in various dimensions, with the distal (aortic) diameter ranging from 4 to 14 mm, while the proximal pulmonary winding diameter ranges from 4 to 6 mm. A phase II clinical trial evaluating the Nit-Occlud has been completed in the United States and results are expected soon.

Other Devices and Device Modifications

In 1995, Grifka et al. (59) reported on the evaluation of a new vascular occlusion device in a canine model. The “Gianturco-Grifka Vascular Occlusion Device” is essentially an oblong nylon bag that is filled with a long, stainless steel spring guide-wire. The length of the wire determines the size of the device, which is available in diameters of 3, 5, 7, and 9 mm. A radio-opaque marker is attached to the proximal end of the bag. The GGVOVOD has been used to occlude a variety of tubular structures, including shunts and pulmonary AVMs, but its design and cumbersome delivery technique make it less suitable for occlusion of the standard type A PDA (58,60,61).

In addition to the aforementioned, a wide variety of devices has been used “off-label” to occlude the patent arterial duct and other vascular communications, including the AMPLATZER Muscular VSD Occluder (62), the AMPLATZER Septal Occluder (63), the buttoned device (64), and the AMPLATZER Vascular Plug (55).

Endovascular Stents

Charles E. Mullins, MD pioneered the introduction of endovascular stents into the armamentarium of the congenital

cardiac interventionalist in the late 1980s and early 1990s (8,65). The most common indications for stent placement include rehabilitation of branch pulmonary artery stenosis as well as treatment of primary and recurrent coarctation of the aorta or aortic arch obstructions. However, stents are also used to rehabilitate stenotic lesions in systemic and pulmonary veins and to maintain patency of structures that would otherwise close, such as the arterial duct or a foramen ovale. Endovascular stents are particularly helpful in locations that are either inaccessible to surgical techniques or where the scarring resulting from surgical intervention is unlikely to achieve an improvement of the lesion, which applies to thin-walled vessels such as distal pulmonary arteries or pulmonary veins.

Virtually all approved stents that are used in the US in transcatheter therapy of congenital cardiovascular lesions have not been designed specifically for these indications and are therefore used on an “off-label” basis. The choice of which stent to use for a particular lesion depends not only on age and size of the patient but also on expected adult dimensions of the vascular structure that is being treated, the morphology of the specific lesion, the presence of side branches that need to be crossed, expected future surgical procedures as well as previous surgical, and transcatheter procedures and their outcome.

An ideal stent would combine a variety of characteristics that are often exclusive to each other and may require opposing design goals:

- Low profile that allows introduction through small delivery sheaths.
- Easy crimpability or availability as premounted stents.
- Possibility for re-expansion with maximum achievable diameter being sufficient to accommodate the growth of a vessel to adult size.
- High degree of flexibility for placement around curved structures.
- Allow rehabilitation of vessels that are overlapped by the placed stent through the stent meshwork/cells (e.g., open cell design).
- High radial force to accommodate very tight and scarred lesions.
- Rounded atraumatic edges that avoid damage to the vessel and the balloon upon which it is mounted.
- Nonexisting or low degree of stent-shortening during expansion.
- Stent material that is MRI compliant, noncorrosive, and does not lead to increased blood levels of metal.
- Low risk of neointimal proliferation, possibly through internal coating.
- Possibility of biodegradable material with a platform to sustain drug coating to minimize tissue reaction.

Unfortunately, the ideal stent does not exist; therefore, a careful decision has to be made on which to use. Dr. Charles Mullins always emphasized that the interventional cardiologist should not create a later surgical stenosis by failure of the stent to be able to be dilated to the adult-sized diameter of the vessel. However, it is important to note that the use of premounted and smaller diameter stents as a “palliative” procedure to relieve critical vascular narrowing in small infants and children, who will have later surgery as a “staged repair” or conduit change, is now a very important treatment option. When judging the suitability of stent implantation, one always has to remember that suboptimal balloon angioplasty may result in impaired interval growth of the pulmonary arterial tree. Furthermore, recent studies have shown that small diameter stents can be intentionally fractured when necessary with the use of high-pressure balloons (66). In addition, surgeons are well equipped to excise or patch a stent when necessary (67).

Table 13.1 summarizes the most important characteristics of those larger diameter stents that are presently most frequently used in treatment of CHD in the United States. The Cheatham-Platinum (CP) stent (NuMED, Hopkinton, NY), as well as its covered variety, is available in the United States for compassionate and investigational use (COAST II trial) only, but is approved outside the United States as the only stent specifically approved for the treatment of CHD,

TABLE 13.1 Stents

Name (Manufacturer)	Material	Max Diameter (mm)	Available Length (mm)	Profile	Radial Force	Flex	Short	Nontraumatic Edges	Crimp	Cells
Genesis XD (Cordis)	Stainless steel	18	19, 25, 29, 39, 59	+	+	0	–	0	++	Closed
Palmaz XL (Cordis)	Stainless steel	25+	31, 40, 50	–	++	–	–	–	+	Closed
IntraStent DoubleStrut LD (EV3)	Stainless steel	18	16, 26, 36, 56, 76	+	–	++	++	+	0	Open
Mega LD (EV3)	Stainless steel	18	16, 26, 36	0	+	++	++	+	0	Open
Max LD (EV3)	Stainless steel	25	16, 26, 36	–	++	+	++	+	–	Open
Cheatham Platinum 8z (NuMED)	Platinum/ Iridium + Gold	25	22–45	–	++	0	–	++	+	Closed

Characteristics of the most commonly used endovascular stents in CHD (United States). Manufacturers listed are Cordis (Cordis, Warren, NJ), EV3 (EV3, Plymouth, MN), and NuMED (NuMED, Hopkinton, NY). The table describes various stent characteristics, ranging from “–” (poor stent characteristic) to “++” (excellent stent characteristic). Max, Maximum; Flex, Flexibility; Short, Stent shortening; Crimp, Crimpability; Cells, Open or closed cell design.

and has favorable design characteristics for the use in native and recurrent coarctation. Covered stents are especially useful for the treatment of ruptured vessels, including aortic aneurysms. Even though the early versions of the Palmaz stent (P108, P188, and P308) (Johnson & Johnson, Warren, NJ) as well as the “ITI Double Strut” and “Double Strut LD” stent (Intra Therapeutics, Inc., St Paul, NM) are still available, they have largely been replaced by the Genesis XD stents (Cordis, Warren, NJ) as well as the EV3 Mega LD and Max LD stents (EV3, Plymouth, MN), and are therefore not listed in this summary. Smaller diameter stents that are used in the congenital pediatric population include self-expandable Nitinol stents, the premounted Palmaz Blue stents (Cordis, Warren, NJ), the premounted Cook Formula 418 stents (Cook, Bloomington, IN), and various coronary stents.

The use of intravascular stents has provided a definitive solution to the problem of overdilation that is frequently required when performing standard balloon angioplasty. There has been extensive favorable experience and up to 15 years’ follow-up in patients with pulmonary artery branch stenosis and systemic vein stenosis. In the single-center series of Mullins and associates at Texas Children’s Hospital, more than 655 stents were implanted in 340 patients with pulmonary artery and systemic vein stenoses. The largest group of patients in this series had lesions involving the central pulmonary arteries in postoperative patients and postoperative central systemic vein or systemic venous baffle stenosis. Many of these stenotic veins had a totally occluded initial lumen; some of the venous channels were intentionally perforated with a wire or long needle. The mean vessel diameter increased from 5 to 12 mm, and there was lasting success, with <0.5% showing restenosis during the follow-up period. The number of complications from the procedure or the stents themselves was minimal.

Melody Valve

Since Dr. Phillip Bonhoeffer et al. (9) performed the first transcatheter pulmonary valve replacement in a human in 2000, more than a thousand of these procedures have been performed worldwide. In January 2010, the Melody valve (Medtronic, Minneapolis, MN) gained FDA HDE approval in the United States (68,69). Its use is indicated for dysfunctional right ventricular outflow tract (RVOT) conduits larger than 16 mm, even though the valve has also been used for other indications (70,71). The Melody transcatheter pulmonary valve is a bovine jugular venous valve that is sutured within an 8-zig, 28-mm Covered CP stent (Fig. 13.3). The valve is mounted on a 18-, 20-, or 22-mm BiB balloon, which is a part of the specifically designed Ensemble delivery system (Fig. 13.3).

Figure 13.3. Melody valve. Transcatheter pulmonary valve implantation. **Left:** Side view of the transcatheter bovine jugular venous valve mounted on a CP stent. **Right:** *En face* view of a bovine jugular venous valve mounted on a CP stent.

HOW TO CREATE, ENLARGE, AND MAINTAIN INTRA-ATRIAL COMMUNICATIONS

Balloon Atrial Septostomy

BAS, introduced by Rashkind and Miller (2) in 1966, is a life-saving procedure and one of the few remaining indications for an emergency catheterization in infants. BAS should be available in every institution that cares for infants with CHD. Because of septal thickening with age, BAS is consistently effective only in infants younger than 1 month of age. The BAS procedure is indicated in all infants with simple transposition of the great arteries (TGA) who are younger than 1 month of age with a restrictive intra-atrial communication, and not otherwise scheduled for immediate surgical correction. Emergency BAS is imperative in any infant with simple TGA who exhibits evidence of acidosis as a result of an inadequate intra-atrial communication. This procedure also may be indicated for palliation in other congenital heart lesions in equally young infants, in whom all systemic, pulmonary, or mixed venous blood must traverse through a restrictive intra-atrial communication to return to the active circulation. These lesions include complex single-ventricle defects associated with hypoplastic right or left ventricles and some instances of total anomalous pulmonary venous connection. BAS is rarely indicated in cases of pulmonary valve atresia and intact ventricular septum (IVS). It can be extremely hazardous in left-sided heart hypoplasia if the left atrium is diminutive, as there is a heightened risk of perforation or avulsion of atrial appendage or pulmonary vein. In such cases, static balloon dilation of the atrial septum may be preferable (72).

The preferable approach for performing a BAS is percutaneously through the femoral vein. In addition, BAS can be accomplished successfully using an umbilical venous approach. For acute, temporary palliation, many of these procedures can be performed under echocardiographic guidance in the neonatal intensive care unit, but whenever possible, the availability of fluoroscopy in the cardiac catheterization laboratory adds an additional safety margin to the procedure. BAS catheters are available from variety of manufacturers and in different designs. The classical Miller-Edwards balloon septostomy catheter (Edwards Lifescience, Irvine, CA) is a single lumen catheter with a fairly compliant latex balloon at the end, that is rated up to 4 mL capacity but can be inflated with larger quantities if required. It requires the use of a 7 Fr sheath and is still in widespread use, even though newer catheter varieties offer more favorable balloon characteristics. Because of the single lumen, it cannot be tracked over a wire and the fairly high compliance often requires large balloon inflations to successfully perform a septostomy, which is a considerable disadvantage especially in smaller infants under 3 kg. Other

catheter varieties include the USCI Rashkind balloon catheter (USCI, Glens Falls, NY), which have a 6 Fr shaft, and the newer NuMED Z5 atrioseptostomy catheters (NuMED, Hopkinton, NY) that are available on a 4 or 5 Fr shaft and can be passed through a 5 or 6 Fr introducer. These balloons have the advantage of being noncompliant at inflation volumes of 1 or 2 mL, which is very important when attempting to tear, rather than stretch the atrial septum. The balloons also have the additional benefit of being able to be passed over a wire.

Once the deflated balloon catheter is introduced into the venous system and while it is observed on fluoroscopy or by echocardiography, it is advanced through the right atrium and through the foramen ovale or small ASD into the left atrium. While continually observed on fluoroscopy and/or 2-D echocardiography, the balloon is inflated with dilute contrast to the maximum diameter of the balloon or, in the smaller atrium, to the maximum diameter tolerated within the particular left atrium. It is essential to determine that the balloon is completely free within the left atrium before initiating the “jerk” across the septum. Failure to do so can result in laceration or even separation of the left atrium from the pulmonary veins. The balloon is pulled rapidly or, better stated, “jerked” across the atrial septum into the right atrium using as forceful and rapid, but at the same time, as short and controlled a pull as possible. Especially when using the fairly noncompliant NuMED atrioseptostomy catheters, it is important to avoid pulling the balloons into the inferior vena cava (IVC), as the rapid “jerk” can easily create a laceration or disruption of the IVC–RA junction. The entire procedure should be performed one to four times or until no resistance to withdrawal of the fully inflated balloon is encountered or until enlargement of the defect and looseness or “flipping” of the septum primum tissue are documented by echocardiography. Following a successful septostomy, there should be an immediate equalization or near equalization of pressures across the atrial septum. Performed carefully with precise attention to details, the procedure carries only a small risk; yet it has the potential for a dramatic improvement in the infant's hemodynamic and symptomatic status.

Blade Atrial Septostomy and Balloon Atrial Septoplasty

In infants over 1 month of age, and certainly for older children who might require an atrial septostomy for palliation of their cardiac defect, the atrial septum usually is frequently too tough or thick for a simple BAS to tear the septum. In 1975, Park et al. introduced the Park Blade Septostomy Catheter (Cook, Inc., Bloomington, IN) and the blade atrial septostomy procedure to obviate this difficulty. A collaborative study from 1978 to 1982 (73) demonstrated the safety and effectiveness of the blade procedure. The indications for blade atrial septostomy are the same as considered for a balloon septostomy or for surgical atrial septostomy that otherwise would be needed in the older infant.

Blade catheters are available with three different blade lengths: 1.0, 1.34, and 2.0 cm. The two smaller blades (the PBS 100 and 200) are available on a 6 Fr catheter, and the 2.0-cm blade (the PBS 300) is on an 8 Fr catheter. Both blade catheter sizes require a sheath one size larger than the catheter shaft for smooth introduction.

The most consistent method of delivering the blade into the left atrium is to pass a long Mullins sheath over a catheter or dilator from the femoral vein through the right atrium, through the septum, (either through the PFO or through a transseptal puncture) into the left atrium. The blade catheter is advanced through this sheath, and the sheath is withdrawn well into the IVC. The blade is opened carefully in the left atrium while it is continuously observed on fluoroscopy. Transesophageal echocardiographic guidance can add an additional safety margin to this procedure.

The tip is directed anteriorly and to either the patient's right or left side. In contrast to the balloon septostomy, the blade catheter is withdrawn slowly in a controlled but at the same time, forceful maneuver until the blade snaps through the septum. The “blading” is repeated four to eight times while changing the angle of extension of the blade as necessary and changing the blade direction from side to side until there is no further resistance to the withdrawal of the fully opened blade catheter.

The blade septostomy is followed by a balloon septostomy. In most patients, this can be accomplished using the Rashkind balloon technique; however, in larger or older patients, when the septum is tough or resistant to tearing, the blade incision can be extended by the use of static dilation balloons placed in the defect and inflated. Alternatively, balloon dilation alone after transseptal placement of a guidewire can be effective in creating or enlarging an ASD. The resultant defect will be somewhat smaller than the balloon or balloons used for dilation, so the balloon catheters must be oversized relative to the final defect diameter desired. As a result of the combined blade and ballooning, equalization of pressures between the two atria as well as a measurable increase in the mixing of the systemic and pulmonary venous blood should occur. In most cases, an adequate and permanent ASD is created, palliating the patient indefinitely or until a more permanent correction is possible. Stenting of the atrial septum has been performed in a few cases to ensure a lasting opening. The blade atrial septostomy can be accomplished in patients of any age or any size. Prior to the introduction of the transhepatic approach, congenital absence or acquired blockage of the IVC had been the only absolute prohibition to a blade atrial septostomy.

With the availability of larger cutting balloons of up to 8 mm in diameter (Boston Scientific, Boston, MA), the combination of static cutting balloon septoplasty, followed by the use of larger diameter static balloons or standard BAS, has become an important alternative to blade atrial septostomy in patients with a thickened atrial septum. The smaller the pre-existing septal defect, the higher the likelihood that the use of cutting balloon will achieve an adequate result (Fig. 13.4). This is especially important if the patient size is rather small making it prohibitive to use even a small PBS 100 blade catheter. If the existing intra-atrial communication is stretched, cutting balloon septoplasty may be unfeasible, and it may be more beneficial to perform a transseptal puncture to start with a “fresh” diminutive opening to facilitate a better result of cutting balloon atrial septoplasty. More technical details are provided in the section on Hybrid Palliation of Hypoplastic Left Heart Syndrome (HLHS), where atrial septal interventions are particularly important and challenging (72).

Transseptal Puncture

Access to left heart structures is required at times to obtain accurate left atrial pressure recordings or to facilitate interventional procedures such as the creation or closure of an intra-atrial communication or balloon mitral valvuloplasty (BMVP). In addition, access to left heart structures from a venous approach avoids the use of larger sheaths in the femoral artery, which can be especially beneficial in small children and infants. Most catheterization laboratories use the standard Brockenbrough transseptal needle, while the use of radiofrequency (RF) energy has added a more controlled technique specifically for infants with small left atria (74).

The Brockenbrough needle is available in sizes of 62 and 72 cm of usable length, and is usually used in conjunction with a transseptal Mullins introducer set (Cook, Bloomington, IN). A fairly stiff exchange length wire is placed in SVC or preferably innominate vein, and the Mullins sheath and dilator are advanced to a position within the SVC. The wire is withdrawn and the transseptal needle is advanced through the sheath to a

Figure 13.4. Septoplasty. RF perforation of the atrial septum followed by cutting and standard atrial balloon septoplasty in a 7-day-old infant with hypoplastic left heart syndrome, intact atrial septum, and a restrictive decompressing vein. Images (from left to right and top to bottom) demonstrate the RF wire across the atrial septum, the coaxial catheter advanced over the RF wire into the LA, and wire position through the coaxial catheter into the decompressing vein. Cutting balloon septoplasty is followed by standard balloon atrial septoplasty and final left atrial angiography demonstrating the newly created intra-atrial communication. An intracardiac echocardiographic probe is utilized in TEE position.

position just 1 to 2 mm below the tip of the dilator. On occasions, difficulty can be encountered when introducing the transseptal needle through the hub or dilator and sheath, at which point the two components should be separated temporarily by 1 to 2 cm to allow passage of the needle through the hub. Once the needle has been positioned appropriately, the whole system is flushed and the needle is connected to a pressure monitoring system. There is usually a 1- to 2-cm separation between the needle and the hub of the dilator and care must be taken to maintain this distance throughout the procedure. Needle, sheath, and dilator are then removed carefully as one unit with the system being gently pointed towards the patient's left scapula (and posterior) when withdrawing from the SVC and sliding along the atrial septum. Any harsh movement or torque should be avoided at this stage as it can create injury to adjacent vessel or chamber walls. Once the unit has passed about two-thirds of the atrial septal length inferiorly, one often notices the tip of the dilator suddenly moving slightly to the left while advancing into the fossa ovalis. At this stage, sheath dilator and needle are withdrawn inferiorly for a further few millimeters just below the limbus of the ovale fossa. The sheath and dilator are then fixed, while the needle is advanced slightly out of the tip of the dilator until it fully engages the dilator. At this point, the whole unit is advanced while carefully observing the recorded pressure tracing and maintaining a left and posterior direction. The operator usually feels a slight "pop" when the needle traverses the atrial septum and this should be

followed by the emergence of left atrial pressure tracing. If any untoward resistance or inappropriate pressure tracings appear, the operator should stop any advances of needle, sheath, and dilator. If a position is unclear, a small amount of contrast can be instilled through the needle.

If a left atrial pressure tracing is obtained, the entire system is advanced slightly further towards the patient's left to allow at least the proximal portion of the dilator to pass through the atrial septum. This is performed in very diminutive steps while maintaining careful observation for left atrial pressure tracings. At this point, the needle is withdrawn just inside the dilator to add additional stiffness to the system and the Mullins sheath is advanced over the dilator and needle across the atrial septum into the left atrium. If at any stage during the procedure, doubt about the accurate position occurs, the system is withdrawn in very small steps until either appropriate pressure recording reoccurs or a small amount of contrast confirms the sheath's location.

An alternative to the use of the classical Brockenbrough needle is the use of RF energy. At the present time, two techniques of RF perforation of the atrial septum are available, depending on patient's size and left atrial size. In larger patients, the Toronto transseptal catheter can be used in combination with the 8 Fr Torflex transseptal sheath and dilator (Both: Baylis Medical Corporation, Montreal, Quebec, Canada). The Toronto transseptal catheter is curved at the end by about 210 degrees to avoid continued perforation of adjacent structures once

the atrial septum is traversed. It also has a slightly increased stiffness when compared to the Nykanen RF perforation wire (Baylis Medical Corporation, Montreal, Quebec, Canada) that is specifically suited to allow tracking of the transseptal sheath across the perforated atrial septum. Initial positioning of the transseptal sheath is very similar to the Brockenbrough transseptal technique. However, instead of using a stiff and forceful needle to traverse the atrial septum, low-power and high-intensity electrical current is used to allow the transseptal catheter to advance through the atrial septum, usually with minimal force and a much lower risk of injuring adjacent structures.

In small infants, especially in neonates with a small left atrium, the curve of the Toronto transseptal catheter is too large to fit snugly into the small left atrium. Therefore, in these patients, a 5 Fr JR catheter is used to obtain an appropriate position along the atrial septum to facilitate RF puncture (Fig. 13.4). A 180-cm 0.035-inch outer diameter coaxial injectable catheter (Baylis Medical Corporation, Montreal, Quebec, Canada) is loaded over a 260-cm 0.024-inch Nykanen RF perforation wire and the RF wire is advanced to the tip of the positioned JR catheter. The use of TEE-guided perforation of the atrial septum has greatly improved the safety and success of this challenging procedure. In infants <3 kg, placing the 8 Fr ICE catheter (Acuson-Siemens Co., Mountain View, CA) transesophageally has been suggested by Hill et al. (75) as an additional form of guidance for the transseptal puncture. Once an accurate position is confirmed with hand injections of contrast through the side-port of a Touhy Borst adapter, RF energy is applied, while also exerting a gentle push on the RF wire. Once perforation has occurred, an orienting injection of contrast can be performed through the Touhy Borst adapter, before advancing the coaxial catheter over the RF wire across the perforated lesion. The RF wire is then exchanged to an appropriate exchange-length wire that can be preshaped according to the size of the left atrium. This positioned wire then facilitates cutting balloon septoplasty, possibly followed by BAS or standard septoplasty using larger balloon diameters, depending on the size of the intra-atrial communication that is required.

BALLOON AORTIC VALVULOPLASTY

The possibility of creating significant aortic regurgitation has always been the main concern when considering balloon dilation of congenitally stenotic aortic valves, especially in infants and small children. In 1984, Lababidi et al. reported for the first time on a series of 23 patients with congenital aortic valve stenosis, in whom the procedure was documented to be safe and effective (31). Despite this report, general acceptance of the technique was relatively slow. One of the fundamental problems of the procedure to this day remains the risk of creating significant aortic insufficiency, which then may accelerate the need for any surgical aortic valve procedure. While this is less of a concern in the adolescent, where all other treatment options are available in such a situation, problems are more significant in the infant who has a moderate degree of aortic valve stenosis, where severe aortic regurgitation may force a surgical procedure to be performed at an age where one would have otherwise preferably waited for the patient to grow.

Several other centers have demonstrated that the results of balloon aortic valve dilation approximated the results of surgical valvotomy but with less risk and less morbidity. However, the disease has very wide morphological variations, ranging from the critically ill neonate with borderline LV and left ventricular outflow tract size and a very dysplastic aortic valve to the young adult with isolated valvar stenosis and well-formed aortic valve.

The decision when to take a patient with congenital aortic valve stenosis to the catheterization laboratory is not always straightforward. Many factors have to be considered including peak and mean Doppler gradients, age and gender, electrocardiogram (EKG) findings, LV function and degree of Left ventricular hypertrophy, symptoms, exercise tolerance, and desire to exercise competitively, valve morphology and preexisting aortic insufficiency, as well as associated lesions such as coarctation or mitral valve (MV) disease. Guidelines for the treatment of congenital aortic valve stenosis in children are derived from the adult population (76), where a peak-to-peak gradient in excess of 60 mm Hg in asymptomatic patients is considered an indication for transcatheter intervention. However, in symptomatic patients, or with the presence of ischemic or repolarization changes on EKG, a gradient of 50 mm Hg should be used. However, peak systolic gradients are only meaningful if LV function is normal. Documented aortic valve stenosis in the critically ill neonate with a dilated left ventricle and poor LV function is an indication for transcatheter intervention irrespective of any obtained transvalvar gradient.

Balloon aortic valvuloplasty is now considered a standard technique performed in virtually any center that offers interventional treatment for congenital cardiac lesions (Fig. 13.5). In contrast to BPV, where the vast majority of patients can be expected not to require any further transcatheter or surgical intervention, aortic valvuloplasty is usually palliative in nature, and not infrequently aimed at delaying an inevitable surgical procedure, be it valve replacement or Ross procedure, until a time when the child has reached close-to-adult size. A surgical series reporting the results of surgical aortic valvuloplasty documented freedom from aortic valve replacement (AVR) of 72% at 10 years and 60% at 18 years (77). This is very similar to the results of transcatheter aortic valvuloplasty where freedom from AVR of 79% at 10 years and 53% at 20 years has been reported (78).

In general, aortic valve dilation is performed retrograde with a catheter introduced into the femoral artery. While an antegrade approach with transseptal puncture offers a slight advantage in maintaining a centered balloon position across the aortic valve during balloon inflation, the technique is more cumbersome and is associated with risk of injuring the MV apparatus with resulting mitral insufficiency, and is therefore not routinely employed. An end-hole catheter is passed from the femoral artery across the aortic valve to a stable position in the left ventricle. A double-balloon technique with the introduction procedure repeated from both femoral arteries may offer advantages for the aortic valve dilation in selected older patients, even though today, the spectrum of available balloons usually allows a successful employment of a single-balloon technique.

The catheter/wire passage retrograde across the stenotic aortic orifice is the most difficult maneuver in the entire procedure, and therefore should ideally be performed only once during the procedure. Before crossing the aortic valve, an aortogram with 25 degrees left anterior oblique (LAO)/cranial angulation of the anteroposterior (AP) and straight lateral projection should initially be performed to exactly delineate the size of the aortic valve annulus, while at the same time demonstrating any angiographic evidence of preexisting aortic valve insufficiency. The exact technique for passing the wire or catheter into the left ventricle varies from operator to operator. A Judkins right coronary catheter curve or multipurpose catheter is used by some operators with success in crossing the aortic valve from this approach. However, the Judkins left coronary catheter may offer advantages in many patients, as the curvature is automatically directed to the leftward and posterior opening of the congenitally stenotic aortic valve. Once the valve is crossed, an end-hole catheter (not Judkins left) is advanced over the wire into the left ventricle, and the wire

Figure 13.5. Aortic valvuloplasty. Balloon aortic valvuloplasty in a 3-month-old infant with congenital aortic stenosis (Gradient: Pre: 92 mm Hg, Post: 25 mm Hg). **Top left and right:** Aortogram in lateral and AP projection profiling the doming aortic valve annulus. **Bottom left:** Balloon inflation centered across the aortic valve with concomitant rapid RV pacing for cardiac output control. **Bottom right:** Aortogram after balloon valvuloplasty documenting absence of aortic insufficiency.

replaced with an extra stiff exchange-length wire with a long floppy tip, which is looped within the ventricle to protect the ventricular apex from perforation by the catheter tip and to minimize ventricular ectopy. A LV angiogram is optional. If an atrial communication is present, hemodynamic evaluation can be performed by advancing a catheter antegrade into the left ventricle with simultaneous pressure recording in the ascending aorta. The same approach is then also used for LV angiography. In neonates and infants, a floppy-tipped coronary wire with a relatively stiff body may be advanced across the valve and allowed to loop in the left ventricle. Care has to be taken to prevent the wire from being ejected from the left ventricle and therefore, once positioned, wire control should be maintained throughout the procedure. By using a floppy-tipped, high-torque guidewire, the wire does not need to be changed, and the first catheter to cross the valve can be the dilation balloon (thus minimizing the period of potential low output). The use of stiffer exchange wires and longer dilation balloons may aid in maintaining an exact position of the balloons across the valve during inflation and, in turn, eliminate the "shear" trauma to the valve from balloon movement during inflation. With the wire secured within the left ventricle, the deflated balloon is manipulated through arterial sheaths and passed retrograde over the wire. We do not believe that direct introduction of the balloon through the skin should have any role to play, as the balloon profile of balloons has considerably decreased, thereby allowing the appropriately sized balloon to be introduced through fairly small sheaths. In addition, it is quite conceivable that the pulling of a deflated balloon directly through the femoral and iliac arteries may cause more harm

to the vessel than using the appropriately sized sheath. Once the balloon is positioned across the stenotic valve, the balloon is rapidly inflated to the recommended maximal pressure and then rapidly deflated.

One difficulty of the procedure is to keep the balloon positioned across the aortic valve during inflation. Once it is inflated, the balloon tends naturally to move towards the ascending aorta because of the ejecting forces created by the left ventricle. It is generally difficult to push against these forces (unless using an antegrade approach), but a longer balloon length aids this process. Adenosine has been used to achieve a temporary cardiac standstill, but its timing in relation to balloon inflation is often difficult to predict. A more controllable method of reducing the cardiac output is through rapid RV pacing (79). The rate of pacing can be adjusted prior to balloon inflation to achieve a drop in blood pressure by at least 50% and these settings are then available to be used during the inflation process. An inflation device that can be operated using a single hand is preferential, as this allows the operator to use the other hand to maintain control of the balloon catheter, making very fine adjustments while the balloon is inflated. The balloon is then immediately and rapidly deflated, with the entire process taking no more than 5 to 10 seconds. Arterial pressures should be monitored throughout the procedure. To limit the potential damage to the aortic valve, only one inflation should be performed provided that the operator is assured that (a) the balloon remained properly positioned in the valve; (b) the balloon was of adequate size; and (c) the waist disappeared. Regardless of the technique, a marked drop in systemic pressure, a rise in LV pressure, and resultant bradycardia may

transiently result. The double-balloon technique using two balloons placed side by side across the valve may minimize this problem, but more importantly one has to avoid prolonged inflations with any technique when performing aortic balloon dilations. With successful valve dilation, after the balloon is deflated, both the blood pressure and heart rate should return spontaneously to normal.

For a single-balloon technique, the initial balloon is chosen with a diameter of about 80% to 90% of the measured aortic annulus diameter. After each set of inflations, the hemodynamic result and the degree of aortic insufficiency are evaluated. If no or only a mild change in the degree of aortic insufficiency has been observed with still a significant residual gradient (>35 mm Hg), repeat dilation valvuloplasty is done with a balloon sized just 1 to 2 mm above the one previously used. Brown et al. (78) recently demonstrated that freedom from AVR was improved when comparing patients with a residual gradient of <30 mm Hg to those with a gradient in between 30 and 39 mm Hg. Even more importantly, freedom from AVR was better in patient with a gradient of <35 mm Hg and having moderate to severe aortic regurgitation. This compared to those with more than 35 mm Hg gradient but only mild aortic regurgitation suggests that the residual gradient may be more important when compared to aortic insufficiency than previously thought.

When using the double-balloon technique, the combined diameters of the two balloons should approximate 1.2 times the measured diameter of the aortic annulus. Because of the extensive manipulation in the left side of the heart and arteries, all these patients are systemically anticoagulated with heparin at the beginning of the procedure.

In the past, the most common complication of aortic balloon dilation was damage to the femoral arteries by the large balloon dilation catheters. This problem has been minimized by newer lower-profile balloon designs, use of the double-balloon technique where required, and diligent monitoring of ACT levels throughout the procedure. When arterial damage does occur, it usually can be managed medically or, rarely, surgically. In small infants, because of the increased risk of femoral artery injury from the introduction of the dilating balloon catheters into the vessels, several other approaches to aortic valve dilation have been described. The prograde approach, first passing a catheter, then a wire, and finally the balloon from the femoral vein to the right atrium, foramen ovale, left atrium, left ventricle, and prograde across the aortic valve is chosen by some. Although frequently successful, this approach has a high incidence of failure in delivering the balloons and, even more disturbing, a significant incidence of damage to the MV apparatus.

Another approach is through a controlled cutdown on the carotid artery. As a result of extensive experience with extracorporeal membrane oxygenation (ECMO) and the safe introduction of cannulae into the carotid arteries, several centers, with the help of pediatric or vascular surgeons, dilate aortic valves in infants from this approach. The approach is direct to the aortic valve, requires less catheter manipulation and less overall time, and has resulted in no reported complications related to the technique. The ideal procedure for the small infant is still to be determined.

With a conservative dilation of the aortic valve, the gradient should be reduced to a gradient ≤ 35 mm of Hg. This usually can be accomplished without inducing significant aortic insufficiency, no more than that seen after surgical valvotomy. Furthermore, as highlighted above, recent data by Brown et al. (78) suggest that the residual gradient may be more important when compared to aortic insufficiency than previously thought, and reducing the gradient to <35 mm Hg may be more important, even if it were achieved at the expense of moderate aortic insufficiency. However, the treatment approach has to

be tailored to the individual patient, and specifically in infants, gradient reductions to <40 mm Hg may be sufficient to delay the need for early aortic valve surgery. The long-term results, like those for surgical valvotomy, will be palliative; however, the catheter balloon dilation procedure is accomplished without a sternotomy or cardiopulmonary bypass with their inherent risks and morbidity. Balloon dilation of congenital aortic valve stenosis in pediatric patients and young adults is now the standard initial procedure for this lesion in most centers.

BALLOON PULMONARY VALVULOPLASTY

With the development of the special, larger-dilation balloons, a transcatheter technique for balloon pulmonary valve dilation was first introduced by Kan et al. (6) in 1982. The technique performed acutely was successful and, at the same time, carried little risk over and above the basic risk of a catheterization. By December 1986, 28 centers, voluntarily reporting to a collaborative registry (VACA), demonstrated the successful and safe application of the technique in more than 680 cases of pulmonary valve stenosis (80). With these data and many subsequent reports of successful use (81,82), balloon dilation has been accepted as the standard therapeutic procedure for pulmonary valvar stenosis. It is applicable to patients of all ages from the newborn period throughout adult life. With its excellent results and low rate of procedure-related complications, maximum instantaneous systolic Doppler gradients of as little as 35 mm Hg, when combined with evidence of RV hypertrophy, should be considered an indication for BPV (83).

The degree of pulmonary valve stenosis is documented by accurate hemodynamic measurements in the catheterization laboratory. However, if the pulmonary valve is not easily crossed, RV angiography should be obtained prior to further attempts at crossing the valve.

The valve anatomy, size, and exact location are visualized angiographically, with standard AP (with some cranial angulation) and lateral being the most appropriate projections. Accurate determination of the valve annulus diameter is obtained using appropriate calibration techniques. With this information available, a long exchange guidewire is passed through an end-hole catheter into a distal pulmonary artery. The left pulmonary artery (LPA) is preferable for this position because of the straighter course from the valve and main pulmonary artery (MPA) to the left. However, in neonates with a patent arterial duct, the wire may be passed through the duct into the descending aorta (DAO). The chosen wire should be fairly stiff to allow the balloon to track over the wire and across the stenosed pulmonary valve. In infants and smaller children, a stiff 0.018 wire with a floppy tip is frequently appropriate for this purpose. However, infants with critical pulmonary stenosis and a closed arterial duct may poorly tolerate placement of a wire or catheter across the valve; therefore, the valve should only be crossed when all equipment have been prepared to immediately proceed with BPV.

McCrindle (84) documented that the optimum balloon diameter should be between 1.2 and 1.3 times the size of the pulmonary valve annulus for a "single-balloon" dilation. Lower balloon to valve annulus ratios are associated with an increased risk of recurrent or residual pulmonary valve stenosis, while ratios in excess of 1.4 are associated with an increased risk of clinically significant pulmonary insufficiency (84).

The choice of balloon catheters that can be used for this procedure is wide and depends to a degree on the individual valve morphology. In general, inflation pressures of more than six atmospheres are rarely necessary in patients with typical valve morphology, and therefore low pressure balloons such as Tyshak II (NuMED, Hopkinton, NY) with a lower profile are

Figure 13.6. Pulmonary valvuloplasty. BPV in a 5-year-old boy with valvar and supra-valvar pulmonary stenosis, using the double-balloon technique to facilitate the use of higher inflation pressures.

the preferred initial balloon types to be utilized. However, the maximum rated inflation pressures decline sharply when using the larger varieties of these balloons. Therefore, high-pressure balloons, such as ZMed II (NuMED, Hopkinton, NY), or the double-balloon technique should be considered in these situations as the primary approach to balloon valvuloplasty (Fig. 13.6). High-pressure balloons may also be more beneficial when dealing with very dysplastic thickened pulmonary valves in the older patient or if there is associated supra-valvar narrowing. In neonates with critical pulmonary valve stenosis and a closed arterial duct, a low profile balloon with fairly rapid deflation characteristics such as the Tyshak II balloon should be used. Very low profile balloons, such as the mini Tyshak balloons (NuMED, Hopkinton, NY), may cross the valve more readily, but their very slow deflation characteristics make these balloons an inappropriate choice in patients who have critical pulmonary stenosis without a patent arterial duct. If the valve cannot be crossed with the appropriate sized balloon, smaller coronary balloons can facilitate predilating the valve to allow the larger balloon to be subsequently passed.

With the wire fixed in place in the distal pulmonary artery, the end-hole catheter is removed and the catheter with its deflated balloon is passed over this wire until the center of the balloon length is positioned exactly at the area of the stenotic valve. The balloon is then rapidly inflated to the pressure recommended by the manufacturer and is observed for the appearance of a circumferential indentation or "waist" in the balloon. Full inflation results in disappearance of the waist. An inflation device that can be operated using a single hand is preferential, as this allows the operator to use the other hand to maintain control of the balloon catheter, making very fine adjustments as the balloon is inflated. The balloon is then immediately and rapidly deflated, with the entire process taking no more than 5 to 10 seconds. Arterial pressures should be monitored throughout the procedure. In contrast to balloon aortic valvuloplasty, more than one inflation is usually performed to assure the operator that (a) the balloon

remained properly positioned in the valve; (b) the balloon was of adequate size; and (c) the waist disappeared early and at low pressures during subsequent inflations. When a single balloon is used, there is a significant drop in both systemic blood pressure and heart rate during inflation. With successful valve dilation, after the balloon is deflated, both the blood pressure and heart rate should return spontaneously to normal.

To avoid the marked drop in systemic blood pressure and to reduce the trauma to the peripheral introductory veins, a double-balloon technique was introduced (85). This technique also allows the use of higher inflation pressures in patients with a large pulmonary valve annulus, where a single balloon would provide an inadequate rated burst pressure. The double-balloon technique uses two separate balloon catheters, each on a smaller shaft and with a smaller balloon "profile." Each is introduced into a separate vein. With this technique, a second exchange wire is introduced from the opposite femoral vein and positioned across the pulmonary valve into a distal pulmonary artery, possibly next to the first wire. Two smaller-diameter balloon dilation catheters are advanced over the separate wires and centered in the valve orifice, and the two balloons are simultaneously inflated. Various formulae have been used to estimate the equivalence of double-balloon to single-balloon technique (83), ultimately resulting in comparison charts that allow choice of sizes of the two smaller balloons, depending on the size that would have been chosen if a single-balloon technique would have been used. However, a combined diameter of 150% to 160% of the pulmonary valve annulus can be used as a guide to choose the appropriate balloon sizes.

Reported success criteria for BPV have been variable. The VACA registry, dating back as much as 15 years, defined a gradient on follow-up of equal to or above 35 mm Hg as procedural failure (86). Holzer et al. (21) defined procedural success as either a reduction of the peak systolic RV/MPA gradient to <25 mm Hg, or a reduction of the valvar gradient by at least 50%, or a reduction of the RV/systemic pressure ratio by at least 50%. However, with pure valve stenosis and a closed PDA, regardless of the initial gradient, one should expect to reduce the pressure gradient across the nondysplastic pulmonary valve to <10 mm Hg by balloon valvuloplasty in most patients, with an equivalent reduction in the RV to systemic pressure ratio.

If the initial results are suboptimal, the balloon size should be increased up to 130% to 140% of the pulmonary valve annulus, and high pressure balloons should be used, after obtaining an intermittent angiographic evaluation, using, for example, a multitrack catheter that is positioned over the *in situ* guidewire in the RVOT. However, it is important to recognize that relief of the valvar stenosis may unmask a dynamic infundibular obstruction in some cases, resulting in a persistent residual RV outflow gradient (Fig. 13.7). This secondary area of obstruction can be documented by pressure recording during careful catheter withdrawal from the pulmonary artery to the RVOT or with simultaneous pressure recordings from a double-lumen catheter or from separate catheters in each of the two areas. Experience has shown that the infundibular obstruction is dynamic and that it will regress with time. This is particularly notable in adult patients undergoing BPV. Fawzy et al. (87,88) reported an incidence of infundibular gradients in excess of 30 mm Hg in 46% of 93 adult patients undergoing BPV. All these patients were recatheterized within 6 to 24 months, documenting a decrease in the mean infundibular gradient from 43 to 25 mm Hg. In <10% of patients, a dysplastic pulmonary valve is encountered, with thickened, redundant leaflets resembling a "cauliflower"; frequently supra-valve stenosis may coexist. This condition is more common in some genetic conditions, such as Noonan's syndrome. A higher-pressure balloon is usually required with a gradient reduction frequently less than what would be

Figure 13.7. Subpulmonary stenosis after BPV. Dynamic subpulmonary stenosis seen on angiography in a 3-year-old child after undergoing BPV. Hemodynamic evaluation after BPV documented no residual valvar gradient, but a 10 to 15 mm Hg subvalvar gradient.

expected with nondysplastic valves. Within the recent multicenter experience from the C3PO registry reported by Holzer et al. (21), acute procedural success was 77%, with independent risk factors for procedural failure being the presence of a genetic syndrome, complex two-ventricle anatomy, presence of supravalue pulmonary stenosis, a hemodynamic vulnerability score of two or more, and the need for balloon inflation above 8 atmospheres.

Procedure-related serious adverse events are rare. In a multicenter registry (C3PO) including 290 patients, Holzer et al. (21) recently reported an incidence of moderate adverse events in 3% of patients and major adverse events in <1%. There was no incidence of procedure-related death, and independent predictors of higher level adverse events included among others, age below 1 month, complex two-ventricle anatomy, two or more parameters of hemodynamic vulnerability, and operator experience of <10 years.

The long-term effects of the procedure have not yet been determined. However, studies so far have documented rates of restenosis between 5% to 11% within 10 years after the procedure (81,82). The risk of recurrence or restenosis may be greater in patients who present in infancy or with very dysplastic pulmonary valves as well as those in whom an undersized balloon was used in the initial procedure. Holzer et al. (21) recently reported an incidence of early reinterventions of 12% in neonates that underwent BPV. So far, reports have not provided evidence to suggest an increased risk of patients requiring pulmonary valve replacement because of pulmonary insufficiency, secondary to BPV. Dr. Charles Mullins pointed out that in the presence of otherwise normal heart and lungs, the regurgitant fraction is usually small and at low diastolic pressure, due to 80% to 85% of the ejection fraction having “diffused completely into the distal pulmonary capillary bed by the end of systole.” However, we have also learned that progressive RV dilation secondary to pulmonary insufficiency should be considered a potential indication for pulmonary valve replacement.

PERFORATION OF THE ATRETIC PULMONARY VALVE

The diagnosis of PA/IVS is usually made within the neonatal period. Pulmonary blood flow after birth is maintained through a patent arterial duct until a more definitive source of pulmonary blood supply can be established. An intra-atrial communication allows the systemic venous return to pass into the systemic circulation. The long-term prognosis of patients with PA/IVS can be extremely poor, especially when a diminutive right ventricle is combined with an RV-dependent coronary circulation with multiple coronary abnormalities. In this situation, patients may require cardiac transplantation early in life. However, while patients with the diagnosis of PA/IVS and a single-ventricle pathway usually have a very poor long-term outcome, the outlook for those patients with a biventricular or a “one-and-a-half ventricle” circulation is much better.

Perforation of the atretic pulmonary valve plate has an important role to play within the available treatment modalities for these patients (74). Achieving antegrade pulmonary flow not only acutely decompresses the right ventricle but more importantly serves as an incentive to facilitate further growth of an initially hypoplastic right ventricle. While a variety of sharp instruments as well as laser-guided techniques have been used to perforate the atretic pulmonary valve, these techniques are often poorly controlled and associated with a variably high risk of creating inadvertent injury to surrounding structures, often with disastrous results. Consequently, the use of RF energy was introduced into therapeutic cardiac catheterization in the early 1990s as an alternative to laser-guided perforation of the pulmonary valve plate (89).

The equipment presently most frequently used to achieve perforation of the atretic pulmonary valve with RF energy is the Nykanen RF perforation wire and the Baylis RF puncture generator (both from Baylis Medical Corporation, Montreal, Quebec, Canada). Suitability for transcatheter RF perforation of the pulmonary valve plate is ascertained by 2-D echocardiography with minimal criteria in most cases being the presence of a tripartite right ventricle as well as a membranous atretic pulmonary valve with a well-formed infundibulum (90). Vascular access is routinely obtained via right femoral venous cannulation. A femoral arterial pressure monitoring line is placed. Initial hemodynamic evaluation includes measurement of RV and systemic arterial pressures, followed by RV angiography with 20-degree cranial angulation of the frontal tubes and standard lateral projection. This allows measurement of the pulmonary valve plate diameter and exclusion of RV-dependent coronary circulation. Further angiography is obtained in the left ventricle in the same projection. The combination of these two ventriculograms allows documentation of the relationship between the blind-ending RV infundibulum and MPA. A 5 Fr Judkins 2.5 right coronary artery catheter is placed below the pulmonary valve plate within the RVOT using a Touhy Borst adapter to allow passage of the RF wire and simultaneous contrast injections. Once the RF wire and coaxial catheter are loaded and accurate positioning is confirmed, RF energy is applied while maintaining a gentle push on the RF wire towards the valve membrane. In most patients, a power setting of 5 W per second for 2 seconds should be sufficient to perforate the pulmonary valve plate. It is important for the operator to be particularly suspicious of creating a false track if high-power settings are required. RF energy is discontinued once the wire has advanced through the valve plate. Appropriate position is confirmed using contrast injection through the Touhy Borst adapter. The coaxial catheter is then advanced over the RF wire into the MPA and the RF wire is exchanged to a 0.014- or 0.018-inch coronary wire, which can be directed either to a position in a distal branch

pulmonary artery or preferably through the PDA into DAO. Even though a wire position in the distal pulmonary arteries or preferably across the PDA must be established, this should not be attempted with the Nykanen RF wire, as it can easily cause perforation of the MPA (74). The use of a coaxial catheter is a significant advantage when comparing the Baylis to the Osyka RF system that is still in widespread use elsewhere. A low-profile balloon valvuloplasty catheter, such as the Mini-Tyshak (NuMED, Hopkinton, NY), with a diameter of about 130% of the valve plate annulus is then advanced over the coronary wire and balloon dilation performed (Fig. 13.8). In cases where the balloon catheter cannot be advanced across the valve, sequential dilation can be performed starting with a lower profile 2.5-mm coronary balloon. Trackability can also be improved through arterial fixation or snaring of the coronary wire (91). Balloon valvuloplasty is followed by assessment of

the pressure gradient across the pulmonary valve as well as the RV-to-systemic pressure ratio, and a final RV angiogram is performed to document the result of the procedure.

Many studies have reported on the outcome of RF perforation of the pulmonary valve and results have been summarized by Benson et al. (92–97). Most series are very small and include less than five patients. The overall procedural mortality is about 8% with incidence of procedural complications being about 15%.

It has been advocated that the combination of ductal stenting with RF perforation in one single procedure may reduce the number of transcatheter interventions and prevent prolonged postprocedural care. Approximately 50% of all neonates undergoing successful perforation and balloon valvuloplasty require additional pulmonary blood flow (98), even though it remains difficult to predict this for each individual

Figure 13.8. RF perforation in pulmonary atresia (PA)/IVS. RF perforation of the pulmonary valve plate in a neonate with PA and IVS. **Top left:** RV angiogram delineating the RVOT. **Top right:** RF wire across the pulmonary valve plate. **Bottom left:** Balloon valvuloplasty with a wire positioned in distal RPA. **Bottom right:** RV angiogram demonstrating the newly created continuity between right ventricle and MPA.

patient. Some authors have suggested to use the tricuspid valve z-score (95), but this has not consistently been identified of being predictive of the need for pulmonary blood flow augmentation. Regardless, after failing to wean from prostaglandin E infusion after 5 to 7 days, one should proceed with either PDA stenting or surgical aortopulmonary shunt placement. If performed appropriately, this technique allows up to 75% of suitable patients to ultimately sustain a biventricular or one-and-a-half ventricle circulation (74).

TRANSCATHETER TREATMENT OF STENOTIC AV VALVES

Mitral Valve Dilation

When discussing balloon dilation of stenotic atrioventricular (AV) valves, it is very important to distinguish between congenitally stenotic AV valves and acquired AV valve stenosis as a result of rheumatic fever. In many countries outside the United States, rheumatic MV stenosis is still a common lesion in children. These acquired valve lesions with commissural fusion lend themselves naturally to a dilation procedure, which has been demonstrated to be effective in children. In contrast, the anatomy of congenital mitral stenosis (MS) is quite variable and is generally less favorable for balloon dilation, although the procedure has occasionally been effective for this lesion. The decision to proceed with balloon valvuloplasty of congenital MS should be based on a complete echocardiographic assessment of MV anatomy.

The MV is approached from the femoral vein using a transseptal approach into the left heart. A variety of techniques has been described that include predilating the atrial septum to allow passing a single large mitral dilation balloon, the passing of two balloons through two large transseptal sheaths, the passing of two balloons over separate guidewires without long sheaths and without the need for specific dilation of the septum, as well as a double-balloon technique using a multi-track system over a single guidewire (NuMED, Hopkinton, NY) (99). The Inoue balloon (Toray Industries, Houston, TX) is a custom-made hourglass-shaped balloon that is available as a complete set, including sheath, guidewire and mandrill. It specifically facilitates balloon valvuloplasty using a single-balloon technique without the use of a guidewire in the left ventricle (Fig. 13.9). The Inoue balloon is available in three sizes, allowing balloon dilation diameters between 22 and 30 mm. Its use has demonstrated success in treating rheumatic MV stenosis (100).

When using a double-balloon technique, the left atrium is entered and one or two separate transseptal punctures are made. Exchange wires are manipulated from the right atrium through previously positioned catheters or long sheaths across the septum, across the MV, and into the left ventricle with the “transition” and floppy portions of the wires looped in the ventricle. It is important to remember that if a guidewire is to be used for balloon dilation, a balloon-tipped end-hole catheter should be initially directed from the left atrium across the MV to lessen the chance of crossing between chordal attachments. Once the wires are in place, either the two long sheath/dilator sets or the two separate “uncovered” balloons are passed over the wires into the left atrium. The balloons are advanced and positioned across the MV. The sheaths are withdrawn off the balloons and the balloons are simultaneously inflated. Again, longer balloons (5 to 6 cm in older children and adolescents) help to stabilize during inflation. The sum of the two balloon diameters equals the measured or estimated maximal normal MV diameter for a patient of that particular body size. The two balloons allow an adequate total balloon diameter for the

much larger mitral annulus without coincident destruction of the entry veins or the atrial septum during balloon passage. As with any interventional catheterization, these patients should be anticoagulated with heparin.

The initial success of transcatheter balloon dilation of congenital MV stenosis appears equal to that of surgical commissurotomy, depending on the MV apparatus. However, the total experience is limited, and the duration of the relief of the obstruction is unpredictable. McElhinney et al. (101) recently described a series of 108 patients with congenital MS who underwent BMVP or surgical intervention at a median age of 18 months. BMVP was effective in creating a reduction of the mean gradient by 38%, while significant mitral regurgitation was identified as a result in 28% of procedures. Overall 5-year survival was 69%, while patients at the later stages of the institutional experience had a 5-year survival of 87%. The early mortality was similar for balloon valvuloplasty and surgical mitral valvuloplasty, while the need for initial MV replacement was a significant predictor of worse acute and long-term outcomes. The 5-year survival free from failure of biventricular repair after balloon valvuloplasty was 75%. While the authors suggested that the initial procedure for congenital MS in patients with either typical congenital MS or double orifice MV should be balloon valvuloplasty, they conceded that the surgical approach is more appropriate in patients with supravalle mitral ring and parachute MV.

While in general a parachute MV is not a contraindication to balloon valvuloplasty, the procedure is probably less likely to be effective when there is a single papillary muscle or severe shortening or virtual absence of the chordal apparatus (the “arcade-type” MV). Ultimately, it is difficult to predict which intervention is the more appropriate for congenital MS and most series report institutional preferences. As such, comparisons between surgical and percutaneous approach are biased at best.

Tricuspid Valve Dilation

Congenital tricuspid stenosis, as well as rheumatic, carcinoid, and rare other types of acquired tricuspid valve stenosis, occur less frequently than MS, but, as with MS, may be amenable to balloon valve dilation. Congenital forms of tricuspid valve stenosis are usually associated with other cardiac lesions and, similar to MV stenosis, are less amenable to balloon valvuloplasty than rheumatic tricuspid valve stenosis. The diagnosis of tricuspid stenosis is confirmed hemodynamically. As much information as possible about the valve anatomy and the exact location of the obstruction is obtained by echocardiography and angiography. The tricuspid valve is approached by passing one or two guidewires across the valve, either into the pulmonary artery or to the RV apex. With the use of the calculated or estimated maximum tricuspid valve annulus diameter according to the patient's body surface area, the balloon diameter or combined balloon diameters are chosen to equal this measurement (except in cases of annular hypoplasia). The dilation balloons are introduced through standard venous sheaths and over the wires. When the balloons are positioned across the stenotic valve, they are inflated simultaneously. Disappearance of the indentations or waists in the balloons at maximal inflation is sought. As with MV dilation, the use of the longer balloons facilitates appropriate positioning and maintaining positioning across the valve during dilation. A successful dilation should eliminate any transvalvar gradient. Experience with tricuspid valve dilation is limited, but, on the basis of even limited experience and minimal risk, this procedure is offered to the appropriate patients before considering surgery for tricuspid stenosis.

Figure 13.9. Mitral “Inoue” balloon valvuloplasty. A 38-year-old woman with rheumatic MV stenosis. Inoue BMVP reduced the mean gradient from 28 to 9 mm Hg with mitral regurgitation increasing from trivial to mild. **Top left:** 28 mm Hg mean Doppler gradient across MV prior to balloon valvuloplasty. **Bottom left:** 9 mm Hg mean Doppler gradient across MV postballoon valvuloplasty. **Top right:** Inoue balloon inflated across MV. **Bottom right:** Mild mitral insufficiency by color Doppler after balloon valvuloplasty.

TRANSCATHETER MANAGEMENT OF COARCTATION, RECOARCTATION, AND AORTIC ARCH OBSTRUCTIONS

Dilation of peripheral arteries was the first therapeutic catheterization procedure and represents yet another area in which the vascular radiologist introduced the techniques. Dotter and Judkins (1) reported on the dilation of atherosclerotic peripheral arteries at the same time that Rashkind and colleagues were working on the atrial septostomy catheter.

The technique for dilation of vessel stenosis uses small, cylindrical, fixed maximal diameter dilating balloons passed over a spring guidewire, positioned across the area of stenosis, and inflated with relatively high pressures. This stretches or tears the area of stenosis up to the predetermined diameter of the balloon. This balloon technique is not only used to treat recurrent or native coarctation of the aorta (Fig. 13.10), but similarly is used for branch pulmonary artery stenoses as well as central and peripheral venous stenoses. As many vessel dilation procedures are associated with immediate recoil and subsequent restenosis, the addition of balloon-expandable

stents has further improved upon the available therapeutic interventional armamentarium and is frequently the treatment of choice in adult patients.

In 1979, Sos et al. (102) first experimented with balloon angioplasty of native coarctation in postmortem specimens and this was followed by some fundamental work by Dr. James Lock in the early 1980s. He performed balloon angioplasty on excised human coarctation segments as well as experimentally induced coarctation in lambs (103,104). He showed that balloon angioplasty achieved its therapeutic result by creating micro- or macroscopic intimal and medial tears over a variable distance in the vessel. These intimal injuries appeared to have healed completely on late pathologic examination, leaving the ballooned segment with a normal looking intima. The studies also documented that a balloon diameter of less than twice the size of the coarctation segment was unlikely to achieve a successful dilation, while diameters greater than three times appeared to carry a higher risk of deep and extensive tears.

Dr. Ronald Grifka et al. (105) and Dr. Charles E. Mullins' group from Texas Children's Hospital set the stage for early evaluation of endovascular stent therapy to treat coarctation (Fig. 13.11). In animal experiments, they implanted Palmaz

Figure 13.10. Coarctation and PDA. A 14-month-old child was referred for elective PDA closure. Coarctation with 30 mm Hg peak systolic gradient was incidentally found during procedure. PDA was closed with 6/4-mm ADO, followed by placement of a 19-mm Genesis XD in DAO, completely abolishing the gradient. **Left:** PDA and coarctation prior to intervention. **Right:** Postintervention.

P308, P188, and P108 stents in the abdominal aorta and documented that stents can be safely redilated after initial stent implantation. Dr. Andrew Redington et al. (106) added to this in 1993 by implanting a self-expandable stent into a 10-week-old girl who had previously had palliative surgery for hypoplastic left heart syndrome. While one should generally avoid endovascular stent therapy in small infants, in some very rare circumstances, the implantation of a low profile stent in very sick infants may be justifiable, even though one has to accept that these low-profile stents are not expandable to adult size and therefore will eventually require surgical removal. In 1995, Suarez de Lezo et al. (107) reported the first large series of stent implantation to treat native and recurrent coarctation in humans using the Palmaz stent and in 1999 Cheatham (108) first reported on a new stent design, the CP stent, which is also available in a PTFe-covered variety. Holzer et al. (109) at Nationwide Children's Hospital recently reported a larger experience of stent therapy for complex aortic arch lesions, which further expanded the indications for transcatheter stent therapy with excellent results (Fig. 13.11).

One of the major difficulties when comparing the various treatment modalities for native or recurrent coarctation of the aorta, such as surgery, balloon angioplasty, and endovascular stenting, is the fundamental lack of prospective, evidence-based data (110). As such, one has to rely on institutional series (110), the results of which are necessarily influenced by not only the skill of the individual interventional cardiologist and cardiac surgeon in the respective institution but also by the common institutional policy and experience in treating these lesions.

Similar to the comparison of surgical and interventional approaches to coarctation, the decision between balloon

angioplasty and primary stenting is often dependent on the individual institutional policy, rather than being guided by evidence-based data. While both balloon angioplasty and endovascular stenting have an important role to play in the primary management of aortic coarctation, there are a number of valid reasons that make primary stenting the more suitable treatment modality, if the size of the patient permits this procedure. First, the results of balloon angioplasty are limited due to elastic recoil of the coarcted segment and the rigidity of an endovascular stent obviously overcomes this problem. Second, the degree of trauma to the aortic vessel wall plays an important factor in the potential development of complications such as aneurysm formation. While balloon angioplasty often requires a degree of overexpansion of the coarctation and adjacent vessel wall to achieve a maintainable result, endovascular stenting allows having a successful result while dilating the vessel wall only to the desired diameter—overexpansion is not required. Finally, a subgroup of longer-segment coarctation or arch hypoplasia typically has a poorer outcome after balloon angioplasty alone.

Even though primary endovascular stenting offers significant benefits, it is usually avoided in small children and infants, because of the potential for injury to the arterial vessels and access sites as well as the higher likelihood of developing in-stent stenosis when stents are only expanded to fairly small diameters. As with any other aspect of interventional therapy, the catheterization laboratory has to be equipped to allow the operator to deal with potential complications that are specific to the procedure performed (Fig. 13.12).

The goal of the procedure is to achieve reduction in the gradient to <10 mm Hg or a 90% or greater relief of the

Figure 13.11. Complex arch stenting. A 15-year-old child with coarctation repair (end-to-end) during infancy had Shone's complex with transverse arch hypoplasia. Placement of a 36-mm Max LD stent in the transverse arch led to a gradient reduction from 22 mm Hg peak systolic to 2 mm Hg peak systolic. **Left:** Aortogram before stent placement. **Right:** Aortogram after stent placement.

Figure 13.12. Iliac rupture. A 9-year-old boy with localized coarctation undergoing placement of a Max LD stent with complete abolishment of the gradient. Upon sheath removal injury to right iliac artery occurred that was treated through implantation of a covered Atrium Cast stent. **Left:** Injured iliac artery with significant extravasation of contrast, **Right:** Same vessel after placement of the covered stent.

obstruction angiographically. In an observational study, Zabal et al. (111) analyzed a cohort of 54 consecutive adult patients who underwent transcatheter treatment for coarctation with the primary endpoint being a composite index of failure, made up of heart-related death, a gradient on follow-up of more than 20 mm Hg, the need for reintervention, or complications such as aneurysm formation. They identified that a residual gradient of more than 10 mm Hg was associated with a significantly higher failure index. While this is not a prospective or randomized study, it does fit with the results of other observational series and appears to be a good guideline when delivering interventional therapy to these patients.

With the present techniques and equipment, dilation and/or stent implantation for native or recurrent coarctation appears to be successful in achieving immediate relief of the obstruction in more than 90% of cases. Holzer et al. (112) recently reported the results of the CCISC registry on stent implantation for aortic coarctation, documenting acute composite procedural success of 96%. However, the cumulative composite procedural success decreased to 86% at intermediate follow-up (3 to 18 months) and 77% at long-term follow-up (>18 months).

Balloon angioplasty alone for native coarctation in smaller children and infants has lower long-term success rates and the results are frequently not well maintained, with up to 66% recoarctation rate. An additional concern when discussing transcatheter interventions for native coarctation is the potentially greater incidence of aortic aneurysm formation in the area of the coarctation dilation. Aneurysms have occurred both immediately and late after the coarctation dilation. Catastrophic events as a direct result of these aneurysms are rare. However, the follow-up data are limited, and the long-term outcome is uncertain, at best. Data from the CCISC registry suggest that the incidence of aortic wall complications after stent implantation for native coarctation on medium-term follow-up is less with stent implantation than with balloon angioplasty or surgery (13% vs. 44% vs. 25%)(113). From several surgically removed segments and from intravascular ultrasound (IVUS) of the area, it appears that both the aortic intima and media are often disrupted, with only the adventitial layer constraining the aortic pressure. Another concern with these aneurysms, particularly following an otherwise successful dilation, is that if subsequent surgery is necessary, it could be more hazardous because of the disappearance of collaterals following a hemodynamically successful dilation. As more follow-up information is gathered regarding dilation of native coarctation, this technique appears more reasonable for discrete lesions in patients over 7 to 12 months of age (114). Continued long-term follow-up is still recommended. In the

larger child, primary stent therapy for native coarctation is a suitable treatment alternative to balloon angioplasty, even though aneurysms can occur with these stent implants. It has been suggested that gradual conservative expansion of these stents be performed over two or three procedures, especially in tight lesions, to reduce the incidence of dissection or aneurysm formation.

The technique itself is relatively straightforward. The coarctation and adjacent aorta are visualized by quantitative angiography, usually using lateral as well as LAO projections. IVUS can further assist the preinterventional assessment of coarctation, and may be specifically useful in the postoperative group of patients (115–117). If balloon angioplasty alone is performed, a balloon of the same diameter as the narrowest aortic diameter adjacent to the coarctation is prepared. A “J” or curved-tip stiff guidewire is positioned retrograde through the coarctation, around the aortic arch, and into the aortic root or occasionally into the right innominate artery. The dilation balloon catheter is passed over the wire and across the area of coarctation. When the balloon is centered in the coarctation, it is inflated to the manufacturer’s listed maximum pressure. The inflation may be repeated several times until the waist in the balloon or the gradient disappears. In smaller children and infants, cutting balloon angioplasty frequently adds an additional treatment alternative in patients where endovascular stent placement should be avoided.

In the slightly larger patient, when the results of the dilation are not satisfactory and where larger sheaths can be introduced into the arteries, intravascular stents can be used to support the dilated segment of aorta. When stents are used, it is imperative that only stents that eventually can be dilated to the full diameter of the adult DAO are used. In smaller patients with an expected diameter below average adult size, the Genesis XD or the Mega LD stents with a maximum expandable diameter of up to 18 mm would be perfectly appropriate. If larger maximum diameters are required, the Max LD, the CP, or older Palmaz XL (Cordis, Warren, NJ) stents with maximum expandable diameters beyond 25 mm are available, even though the (covered) NuMED CP stent is approved in the United States under an investigational protocol only (COAST/COAST II). If aortic arch vessels must be crossed, the Mega or Max LD stents offer additional advantages because of their open-cell design, which can be expanded to avoid having the side branches of the aortic arch covered by the cells of the stent wire mesh (Fig. 13.13). In contrast, the ePTFE-covered variety of the CP stent is specifically useful for very tight coarctation where an increased risk of injury to the aortic wall is expected as well as in the adult population where catastrophic aortic rupture

Figure 13.13. Three-dimensional (3-D) rotational angiography of open cell stent extending over arch vessels. 3-D reconstruction of a rotational angiogram taken in a 3-year-old child with complex CHD who underwent stent placement of the transverse arch using a 26-mm Mega LD stent (no residual gradient), completely opening the cells to the single side branch using a 10-mm balloon.

has been reported (118–120). Stents implanted in children can gradually be expanded to adult size in subsequent transcatheter procedures to accommodate a child's growth. It is hoped that the prospective enrollment of patients undergoing balloon angioplasty, stent therapy, or surgical treatment in the CCISC, organized by Dr. Thomas Forbes in Detroit with participating centers worldwide, will help shed light on this subject.

Transcatheter management of coarctation in the adult has some important differences when compared to its management in the younger child. For example, limiting factors in younger children when considering endovascular stent therapy, include the potential for injury to the arterial vessels and access sites due to the need for larger sized hemostatic sheaths as well as the higher likelihood of developing in-stent stenosis when stents are only expanded to fairly small diameters. These problems are of a much lesser concern when dealing with an adult. The goal of the interventional procedure in adults is similar to children: To achieve reduction in the gradient to <10 mm Hg or a 90% or greater relief of the obstruction angiographically.

It has been advocated that the risk of catastrophic aortic injury during or after balloon angioplasty and/or stent placement in the adult (118–120) is higher than what would be expected in the younger child, especially when treating primary coarctation. In the adult, coarctation or recoarctation do not always have the morphological correlate of a “high grade” and “tight” stenosis. Many adult patients with systemic and exercise induced hypertension may present with “just” a 20 to 30 mm Hg upper-to-lower limb blood pressure gradient with an angiographic discrepancy between coarcted segment and the aorta at the diaphragm of not more than 30% to 50%. To achieve an adequate result with balloon angioplasty alone, one would ideally have to expand the area to at least twice the size of the coarctation segment (103,104). However, using this as a guide would lead to significant overdilation of not only the coarcted segment but also the adjacent “healthy” aorta. Primary stent therapy is therefore the treatment of choice in adults with primary or recurrent coarctation, as it not only avoids the need for overexpansion but also has a lower risk of recurrence when compared to balloon angioplasty.

While the risk of catastrophic aortic injury cannot be eliminated, it can be minimized through the diligent use of diagnostic techniques such as IVUS (115,117). IVUS allows to evaluate the integrity and structure of the aortic wall above, below, and within the coarcted segment. This not only identifies areas with medial and intimal disruption as could relate from a previous attempt at balloon angioplasty but it also allows clear definition of the extension of the abnormal vessel wall, thereby allowing choice of a stent that is of sufficient length to cover the full length of the abnormal vasculature.

Some institutions advocate preexpansion of the coarcted segment as a means of testing aortic wall compliance prior

to stent implantation. However, this has the disadvantage of potentially extending a intimal-medial tear into healthy vasculature that subsequently may not be covered during stent placement, therefore potentially acting as a “nidus” for aneurysm formation, especially at the areas immediately adjacent to the placed stent. In adults with very “tight” coarctation, it may be beneficial to expand the aorta not to the full intended diameter in a single procedure but instead adopting a staged approach where the stent is dilated over two or three sessions up to its desired final diameter, thereby allowing the aorta to heal between interventional procedures, with a reduced risk of catastrophic aortic wall injury. However, even with a very careful and considerate approach, the risks of treating adult coarctation cannot be fully eliminated and therefore whenever possible, the availability of an approved covered stent variety as a primary or rescue intervention could potentially enhance the safety of these procedures (Fig. 13.14). Covered stents have also been successfully used to exclude aortic aneurysms at the site of (re)coarctation (Fig. 13.15).

It is important to minimize the potential risk of aneurysm formation and other vascular complications after transcatheter therapy of (re)coarctation. The freshly injured vessel wall should be protected from any hypertensive strain and as such, at least temporary placement of the patient on antihypertensive medications such as beta-receptor blockers (even in the normotensive patient), may potentially reduce the incidence of early vascular complications after transcatheter therapy. During follow-up, it is important to investigate the potential development of aneurysms at the site of interventional therapy, which can occur even after stent therapy. A multislice CT scan or MRI should be performed within 6 to 12 months after the interventional procedure.

REHABILITATION OF (BRANCH) PULMONARY ARTERY STENOSIS

Transcatheter therapy of all varieties of branch pulmonary artery stenoses is a widely accepted standard procedure, in large part because most of these lesions are not amenable to surgical repair. However, rehabilitation of branch pulmonary artery stenoses can be one of the most challenging tasks in congenital pediatric patients. Transcatheter therapy has to strive to achieve the optimum possible outcome that sometimes requires repeated and staged procedures to achieve some improvement for an individual complex patient. The treatment modalities available include the use of cutting balloons, standard balloon angioplasty, or the placement of endovascular stents.

The individual success of treating these lesions is sometimes difficult to assess, but in patients with a biventricular

Figure 13.14. Coarctation in pregnancy. A 34-year-old pregnant woman was hospitalized during her 24th week gestation with severe systemic hypertension. Evaluation demonstrated severe coarctation of the aorta. Significant concern for fetus and mother lead to transcatheter placement of a covered NuMED CP stent, with complete abolishment of the gradient. Fluoroscopy time was minimized and appropriate radiation protection measures were taken. **Top:** Aortogram demonstrating near interruption before stent placement. **Bottom:** Aortogram after stent placement.

circulation, a reduction in the RV to systemic pressure ratio is a good indicator for a successful outcome. Individual pressure gradients to branch pulmonary arteries may be less meaningful, and in fact angiographically significant branch pulmonary artery stenoses can be associated with surprisingly low-pressure gradients, especially for isolated lesions and in the presence of significant pulmonary insufficiency. However,

when assessing these gradients across individual stenoses, it is important to avoid a catheter-induced damping and therefore the use of pressure wires such as the RADI pressure wire (Radi Medical Systems, Wilmington, MA) may aid in accurately assessing the hemodynamic data. The angiographic appearance of the vessel before and after transcatheter intervention is equally important, and while one should strive to aim to achieve a “normal” vessel diameter, frequently the percentage of improvement in the anatomic measured stenosis is a good outcome parameter. Rotational angiography with 3-D reconstruction is a new tool that is in particular suited for patients that require complex pulmonary artery rehabilitation. The 3D reconstructions allow to visualize the complete pulmonary artery tree and the best angulations can be chosen to profile individual lesions (Fig. 13.16). This not only provides better imaging of individual lesions but may also lead to a reduction in the overall amount of contrast needed, especially in patients who require multilevel pulmonary artery rehabilitation. The amount of contrast for individual rotational angiograms can be further reduced by using rapid RV pacing during the rotational acquisition.

While standard balloon angioplasty can be performed using a normal balloon-over-the-wire technique, it is frequently helpful to place long sheaths towards the area of intended interventional therapy to facilitate simultaneous therapies of adjacent lesions, balloon exchanges, and subsequent placement of stents if required (Fig. 13.17). In many patients, especially in adults, placements of long sheaths from a femoral venous approach may be difficult. Therefore, alternative approaches should be considered. Internal jugular venous or transhepatic approaches offer the advantages of eliminating some of the double-S-curves that have to be traversed from a femoral venous approach, while also using a shorter sheath length and allowing improved “pushability” of the catheter.

Standard balloon angioplasty alone rarely achieves a sustainable long-term improvement to an individual stenosis and as such is usually only performed in situations where other forms of transcatheter treatment are not available or where the size of the patient or vessel prevents the use of endovascular stents that can be expanded to adult size. No absolute rules exist for determining the correct balloon size; it appears that the balloon should preferably be larger than two times the diameter of the stenotic segment while avoiding exceeding a diameter of three times the actual narrowing. However, when using standard balloon angioplasty, “overdilation” of a vessel is frequently required to achieve an adequate outcome. In very resistant stenoses, the use of high-pressure balloons should be employed, rather than exceeding the size of the dilation balloons. Cutting balloon angioplasty is available for maximum diameters of up to 8 mm and is a suitable alternative to endovascular stenting especially in small distal pulmonary arteries (121,122). It is frequently beneficial to “score” very tight stenoses that can be followed either by standard balloon angioplasty or by endovascular stent placement if required.

Standard balloon angioplasty of pulmonary branch stenosis has not been highly successful at correcting the lesions and many of the vessels that initially are dilated satisfactorily reconstrict immediately (recoil) with the deflation of the balloon or, if not immediately, a short time later. Few of these dilated vessels are maintained at a normal diameter. The true success rate at achieving a vessel of normal diameter with no gradient is <20%; at the same time, there is a definite morbidity and even mortality with the procedure. It is not possible to determine in advance which case will be successful, so the procedure is often performed as a therapeutic trial. Frequently, pulmonary artery rehabilitation is a staged procedure, where reinterventions are not necessarily a sign of procedural failure, but more importantly reflect a consciously chosen staged therapeutic strategy with frequent early reinterventions to

Figure 13.15. Adult coarctation with aneurysm. A 23-year-old man who underwent GoreTex patch augmentation earlier in life and subsequently developed recoarctation with a 22 mm Hg peak systolic gradient and associated posterior aneurysm. Placement of a cove red CP stent completely abolished the residual gradient and excluded the posterior aneurysm. **Top left:** Aortogram before stent placement. **Bottom left:** Aortogram after stent placement. **Top right:** IVUS before stent placement demonstrating the aortic aneurysm. **Bottom right:** IVUS after stent placement with complete exclusion of the aneurysm.

achieve optimum pulmonary growth. This was highlighted in the results from the C3PO registry where 22% of patients required early reinterventions within the first 3 years of the procedure (20).

The clinical use of intravascular stents in patients with congenital heart lesions was introduced in 1989 by Mullins and colleagues with the use of large Johnson and Johnson Interventional System (JJIS; Sommerville, NJ) iliac stents in branch pulmonary artery and central systemic vein stenoses. The experience with stents in these lesions has significantly changed the approach to branch pulmonary stenosis. Results in eliminating any gradients and opening the vessels to their normal diameters have been excellent (8). The implant dilation does not require overdilation of the vessel to achieve a normal

end diameter. The initial results are often sustained over years. In addition, it has been demonstrated that if the appropriate stents are implanted initially, these stents can be dilated further in the future up to the adult diameter of the vessel. In the 25 years since their introduction for this use, intravascular stents have become the primary mode of therapy for branch pulmonary artery stenoses in most large institutions that provide care for congenital heart patients.

Implanting stents that may not be expandable to adult size (such as premounted stents) may be indicated in certain infants and small children undergoing a “palliative” procedure. Holzer et al. (123) recently presented a series of pulmonary arterial stent implantation in children weighing <15 kg and documented that stent implantation may prevent or defer

Figure 13.16. Three-dimensional (3-D) reconstruction of rotational angiography of pulmonary arteries. A 5-year-old girl with TOF-PA-MAPCAs who underwent unifocalization without VSD closure at 6 months of age, followed by two surgical reinterventions and subsequent interventional catheterization within the following 12 months. 3-D rotational angiography facilitates better delineation of an RLL branch PA stenosis (arrows). The image can be rotated until the lesion is best profiled and the allowable angles are displayed (asterisks) that then allows the operator to choose the same angulations for 2-D acquisitions.

the need for subsequent surgical intervention to a time when this can be performed with a lower risk. Similar results were documented in a larger series by Stanfill et al. (67). Furthermore, *in situ* stents may not necessarily present a major difficulty for the surgeons and can be excised or patched where required (67,123). While this may be challenging, it may present the preferred treatment alternative for selected patients. Furthermore, the meshwork of small diameter stents can be potentially fractured using ultra-high-pressure balloons, as recently shown by Maglione et al. (66). This would then allow implantation of stents that can be expanded to adult diameter to accommodate growth of a child and vessel.

The delivery and implantation of intravascular stents in the branch pulmonary arteries are performed through the use of long sheaths and these procedures are usually a fairly complex undertaking. An end-hole catheter is advanced well beyond the lesion to be treated and is replaced with a stiff exchange wire. Appropriate and diligent guidewire positioning is a key to successful stent therapy. A long sheath/dilator large enough in diameter to accommodate the stent mounted on the appropriate delivery balloon is passed over the wire beyond the area of stenosis. This is usually one of the most challenging parts of the procedure and may require changing the approach from femoral venous to internal jugular or transhepatic in selected patients. The chosen long sheath should be kink-resistant and reinforced if possible, such as the Super ArrowFlex sheath (Arrow, Reading, PA), but these suitable sheaths are presently not available in all sizes that would accommodate larger sized balloon-stent combinations, as required in many adult patients. The dilator is then removed over the wire, leaving the sheath and wire in place. The balloon with the mounted stent

is advanced over the wire and through the long sheath to the area of stenosis. The sheath is withdrawn off the balloon/stent; when the stent is verified to be in the exact position, the balloon is inflated, expanding the stent into the lesion and with deflation of the balloon, fixes the vessel at the dilated diameter (Fig. 13.18). During stent positioning, angiography can either be obtained through the sidearm of the long hemostatic sheath or by using an additional angiographic catheter advanced from a separate venous entry site. In order to achieve precise delivery and positioning of the stent, specialized balloon delivery catheters are often helpful. The BIB balloon catheter allows adjustment of the partially deployed stent after inflation of the inner balloon alone, before full deployment using the outer balloon. When expanding the stent to a diameter ≥ 12 mm, the BIB catheter is chosen. The addition of rapid RV pacing also reduces systolic stent movement during deployment.

Pulmonary artery rehabilitation requires a high amount of technical expertise and is not without risks. The results from the C3PO registry documented an incidence of high severity adverse events of 10% in 1,315 procedures (20). Independent risk factors for high severity adverse events were age below 1 month, two or more indicators of hemodynamic vulnerability, use of cutting balloons, and operator experience of <10 years. The use of cutting balloons likely reflected the severity of the underlying lesions, rather than cutting balloons themselves being a risk factor for adverse events. The study also found that technical complications such as stent migration were more common for proximal pulmonary artery lesions, while, for example, reperfusion injuries (Fig. 13.19) as manifested through bleeding from the endotracheal tube were more common for lobar or mixed lesions. Acute changes in distal PA pressures of more than 150% and a mean distal PA pressure of more than 20 mm Hg have been found to be risk factors for reperfusion injury (124). In patients with multiple pulmonary artery stenosis, it is therefore often important to treat as many lesions as possible, allowing a decrease of the pulmonary artery pressures rather than treating only individual lesions that then may lead more readily to a reperfusion injury in the treated segment.

TRANSCATHETER MANAGEMENT OF PULMONARY VEIN STENOSES

Surgical as well as transcatheter interventions for pulmonary vein stenoses have a uniformly bad long-term outcome (125,126). Pulmonary vein stenoses are frequently not isolated. Transcatheter interventions, whether (cutting) balloon angioplasty or endovascular stenting, are often performed as a “last resort” in patients in whom no other treatment alternatives are available before considering heart-lung transplantation. These procedures are technically challenging and have a higher than average associated procedural risk. The procedures are often acutely successful but restenosis is observed in the majority of cases. Attempted dilation of these lesions may be recommended in an infant or child who is severely symptomatic. The experience with intravascular stents in pulmonary vein stenosis to date has had no better medium- or long-term results than (cutting) balloon angioplasty alone, but has been associated with a high percentage of complications including systemic stent embolization. However, in selected patients, short-term results of endovascular stenting may be superior to cutting balloon angioplasty and as such may serve as a temporizing measure in critically ill children (Fig. 13.20). Stents have been surgically placed into pulmonary veins under direct vision as well as during brief ECMO support as “hybrid” procedures. The ultimate prognosis of these lesions remains poor. Where transseptal access is required and patients are of

Figure 13.17. Pulmonary atresia with ventricular septal defect (PAVSD). Major aortopulmonary collateral arteries (MAPCAS)—PA rehab of multiple lesions. A 2-year-old girl with PAVSD and MAPCAS, RLL and Right middle lobe (RML) stenosis (A). A long braided sheath is placed in the proximal RPA with wires positioned in both RML and RLL branches to allow PA rehabilitation in quick succession. Initially cutting balloon angioplasty is performed of RML (B), then cutting balloon angioplasty of RLL, followed by simultaneous standard BA of both RML and RLL (C), with good angiographic result (D, trivial LLL aneurysm).

appropriate size, the use of steerable transseptal sheaths can significantly improve access especially to the right pulmonary veins.

TRANSCATHETER MANAGEMENT OF SYSTEMIC VEIN STENOSES

Dilation of stenosed systemic veins, particularly those narrowed after surgical or other interventions, often is acutely successful and carries little risk. Zahn et al. (127) recently demonstrated the feasibility of transcatheter interventions even in freshly operated lesions. The surgical alternative for these lesions is poor to nonexistent. Like pulmonary branch stenosis, the results are not uniform or predictable. As with balloon dilation of other vessels, there is immediate hemodynamic, anatomic, and symptomatic improvement. However, stenosis recurs in many cases. The technique for dilation of

systemic veins, as with the other vascular balloon dilation procedures, involves crossing the stenosed lesion with a catheter and exchanging the catheter for a wire over which the dilation balloon (or balloons) can be advanced across the lesion. The balloon size varies between two and three times the diameter of the stenosed segment. The balloons are inflated in the lesion to the pressure recommended for the particular balloons. Balloon angioplasty is frequently the preferred intervention when fairly fresh thrombotic material is responsible for the stenosis, as placement of endovascular stents often does not offer additional advantages due to protrusion of thrombotic material through the struts of the placed stent (unless covered stents are used). However, if a vascular stenosis is the cause of an acute vascular thrombosis, stent implantation is usually preferable to balloon angioplasty alone (128).

Similar to results seen in pulmonary artery branch stenoses, the incidence of restenosis is high. Therefore, primary therapy for the more long-standing venous lesions has become the implantation of intravascular stents. In many patients, the

Figure 13.18. “Kissing” stents for bilateral branch PS. Bilateral branch pulmonary artery stenosis after repair of tetralogy of Fallot. Implantation of “kissing” stents to the PAs abolished 25 mm Hg gradients to the branch PAs and reduced the RV/systemic pressure ratio from 60% to 35%. **Top left:** RPA origin stenosis. **Top right:** LPA origin stenosis. **Bottom left:** Simultaneous expansion of “kissing” stents (Genesis XD and Max LD). **Bottom right:** Angiographic result after stent deployment.

use of RF energy combined with the subsequent placement of covered stents may allow the recanalization of even completely obstructed venous structures (Fig. 13.21) (74). As with any other lesion, stents are chosen to be expandable to adult size, and therefore usually include the Genesis XD or the Max/Mega LD stents, or the covered CP stent, if available. The venous stent delivery procedure is similar to other intravascular stent deliveries in congenital heart lesions with the stents delivered over a stiff wire and through a long sheath. For stent delivery, a single balloon of a diameter similar to that of the adjacent nearest normal vein is used. Results of central venous stent implantations have been excellent. No adverse reactions or long-term complications of the stents have occurred. Some venous restenoses have occurred when stents were dilated to a diameter significantly larger than the adjacent vessel at the time of implant.

In these instances, the lumen within the stent “remodels” with neointima to the size of the normal adjacent vessel.

TRANSCATHETER THERAPY AFTER “ATRIAL SWITCH”

Prior to the establishment of the “arterial switch procedure” as the primary technique to treat patients with TGA, a large number of patients have been palliated using a modified Mustard or Senning procedure. These patients have continued to survive into adulthood, often with very minimal early limitations in their overall cardiopulmonary exercise capacity. However, it has gradually become very clear that the “atrial

Figure 13.19. Reperfusion injury after PA rehab. switch” procedures have not “corrected” these patients, but instead have created a long-term palliation with very favorable early results. As a result of their often fairly normal overall cardiovascular status, many patients have been “lost to follow up” or have only been followed up in large intervals without very detailed diagnostic studies being performed on a regular basis. However, as these patients have survived into adulthood, more patients have become symptomatic from problems that are related to the early palliation and are frequently amenable to transcatheter and/or electrophysiological therapy. These problems include systemic and pulmonary venous baffle

limb obstructions, baffle leaks, left ventricular outflow tract obstruction, atrial and ventricular arrhythmias, conduction anomalies, and sudden death. In addition, RV function is frequently found to be reduced, often manifesting itself with an increasing amount of tricuspid regurgitation.

The workup prior to any transcatheter intervention should include an exercise study with documentation for potential arrhythmias or desaturations on exercise, a transthoracic or preferably transesophageal echocardiographic evaluation with documentation of any potential baffle leak or baffle obstruction, and Holter recording. An MRI will enhance the

sensitivity in detecting baffle leaks and baffle obstructions, while also providing RV functional parameters. The electrophysiology team has to be closely involved in preparing these procedures, deciding upon the best physical location (adult or pediatric hospital) and the order in which each individual part of the procedure is performed. This may not only include the pediatric, but in some patients also the adult electrophysiology team who may have greater expertise in, for example, complex pacing lead extractions. For example, a patient with a permanent pacemaker and a lead fracture may benefit from lead extraction at an adult center. The same patient could then be transferred with a temporary pacing lead to the specialized congenital interventional center, where stent therapy of a coexisting SVC baffle limb stenosis is performed, which then allows the pediatric electrophysiologist

to place new transvenous pacing leads through the newly “opened up” SVC.

In general, most patients will usually undergo a combined procedure, during which the interventional cardiologist initially performs a full left- and right-heart hemodynamic evaluation (ideally obtaining jugular venous as well as femoral venous access), which will give some idea of potential pulmonary or systemic baffle limb stenoses. Angiograms of SVC, IVC, right atrium, as well as pulmonary arteries further delineate any areas of stenosis, while also documenting the presence of any baffle leaks. TEE evaluation should be performed during the procedure to better delineate the baffle leaks and specifically their distance to AV valves as well as documenting the location of any pulmonary venous baffle limb stenosis. If multiple abnormalities are identified, it is very important to

Figure 13.21. Recanalization of SVC obstruction. involve the cardiac surgical team during the procedure. That allows determining which lesions may require surgical revision, while deciding at the same time whether other lesions could/should be addressed during the transcatheter procedure. The pediatric electrophysiologist usually follows the interventional cardiologist with an evaluation of AV conduction as well as an electrophysiology study to detect atrial and ventricular arrhythmias. This is then followed by either implantable cardioverter defibrillator (ICD) or pacemaker implantation if required, frequently through the newly stented SVC.

Many cardiologists have in the past adopted a “wait and see” approach when faced with baffle limb obstructions or baffle leaks. However, even though an obstructed SVC baffle limb with a well-formed collateral circulation in an asymptomatic patient may not necessarily cause any immediate problems, rebuilding this vessel not only prepares these patients for the potential of ICD or pacing leads placed later in life but also prevents the baffle stenosis to become completely obstructed, which would pose a higher challenge for any transcatheter management needed in the future. Symptomatic SVC obstructions do benefit from transcatheter management in any patient, while any IVC baffle limb stenoses, if left untreated, have the potential of impairment of hepatic flow characteristics with secondary hepatomegaly and ascites. Pulmonary venous baffle limb stenoses may lead to pulmonary congestion as well as elevated pulmonary arterial pressures and should therefore be treated with the same degree of aggressiveness as MS in a patient with an otherwise normal intracardiac anatomy. Finally, baffle leaks are potential causes for right-to-left

shunting and paradoxical embolism, which can be a particular problem in patients with pacing or ICD leads and/or frequent atrial arrhythmias. Baffle leaks can also lead to desaturation during exercise or even at rest, thereby may contribute to a reduced exercise tolerance, while moderate shunts add unwanted volume loading to the already reduced RV function. At this institution, we have therefore adopted an approach that attempts to eliminate any residual anatomic or morphological abnormalities as much as possible through transcatheter therapy, which has been documented to be an excellent form of therapy for these lesions with very favorable results (129).

SVC baffle limb rehabilitation is best preformed using an internal jugular venous approach, placing a stiff wire with a floppy tip within the left ventricle. Some SVC baffle limb stenoses may require high pressures during balloon expansion and frequently the placed stents must be further expanded using high-pressure Mullins balloons (NuMED, Hopkinton, MA). Stents that are expandable to diameters in excess of 18 mm, such as the Max LD stent (EV3, Plymouth, MN) or the (covered) CP stent (NuMED, Hopkinton, MA), are most suitable to treat these baffle limb obstructions. Stents should only be placed across a baffle leak after the leak itself has been occluded using a transcatheter device (Fig. 13.22). Where approved and available, a combination of baffle leak and obstruction can be more readily treated using covered stents. Pulmonary venous baffle limb stenoses can be addressed either by a transeptal approach or by using a retrograde aortic approach through right ventricle and tricuspid valve. The short length of these lesions usually makes them less amenable to intravascular

Figure 13.22. Mustard baffle leak and stenosis. A 25-year-old patient with a history of Mustard atrial switch procedure for TGA. Hemodynamic evaluation demonstrated a SVC baffle limb stenosis with near-interruption and a 10 mm Hg mean gradient as well as a stenotic SVC. Additionally, a baffle leak was identified at the inferior end of the SVC baffle. **Top:** SVC angiogram delineates the severe SVC baffle limb stenosis and the baffle leak to the right of the stenotic area. **Middle:** SVC angiogram after occlusion of the baffle leak using an 8-mm ASDO and placement of a 36-mm Max LD within the SVC baffle limb, demonstrating no residual angiographic shunt and significantly improved SVC baffle limb. **Bottom:** Angiogram in SVC after placement of two additional Max LD stents in SVC, thereby rehabilitating the hypoplastic SVC from innominate vein insertion to baffle limb (mean residual gradient 1 mm Hg).

stent therapy, but some improvement can be achieved using high-pressure balloon angioplasty.

The experience of managing these patients at our institution using a combined team approach was presented by Holzer et al. (130) in 2006 (Fig. 13.23). Between December 2002 and April 2006, 81% of all patients who were followed after atrial switch procedure underwent transcatheter evaluation. Electrophysiologic or pacing procedures were performed in the same setting in 15 patients. SVC baffle limb stenosis was found in 75% of patients, while IVC baffle limb stenosis was seen in about 11%. Seven percent of patients had a pulmonary venous baffle limb stenosis, while 57% of patients had baffle leaks. Only three patients had none of the aforementioned abnormalities. Stent therapy was performed for 19 SVC baffle limb obstructions and 2 IVC baffle limb obstructions. Devices for baffle leaks were implanted in 11 patients, while 5 patients received a covered stent for a combination of baffle limb stenosis and leak. One patient underwent balloon angioplasty of a pulmonary venous baffle limb stenosis and three patients had RF perforation of a completely obstructed SVC baffle limb. Most patients with pulmonary venous baffle limb stenosis underwent surgical revision—the same applied for three patients with large baffle leaks and insufficient distance to the AV valves. After stent implantation, the gradient across the baffle limb was reduced significantly from a mean of 3 mm Hg to a mean of 1 mm Hg, while the mean diameter improved significantly from 8.3 to 18 mm. Transcatheter baffle leak occlusion was performed or attempted in 17 patients, while three patients had unsuitable locations of the baffle leak, requiring surgical revision. Complete closure of the baffle leaks was achieved in about 82% of patients. Trivial residual leaks were seen in two patients, usually around small right atrial trabeculations. Complications were rare and only encountered in two patients, including atrial tachycardia requiring medical management in one and temporary complete heart block (CHB) in another. Over a follow-up period of up to 3.7 years, one patient underwent a repeated intervention for closure of a residual baffle leak after surgical baffle revision, while three patients underwent surgical correction for large baffle leaks or pulmonary venous baffle limb stenoses.

These data demonstrate clearly that patients after atrial switch have significant pathology that can be treated in the catheterization laboratory. Patients after “atrial switch” procedure require a team approach to identify and treat any residual anatomic lesions. Transcatheter and electrophysiologic therapy have important roles within the multidisciplinary management of these patients.

DEVICE CLOSURE OF SEPTAL DEFECTS

Transcatheter Closure of Atrial Septal Defects

At the present time, the AMPLATZER Septal Occluder is the most commonly used device to close intra-atrial communications worldwide as well as in the United States, ranking superior with regards to closure rates, rates of complications, and ease of use. However, prospective clinical trials that compare this device with other available devices in a controlled and randomized fashion have not been conducted.

Preparation for Transcatheter ASD Closure

Transcatheter closure of ASDs is usually performed under general anesthesia using TEE as guidance for device deployment and delivery. However, studies have documented that ICE is equally suitable for echocardiographic guidance, thereby allowing these procedures to be performed under conscious or deep sedation in older children and adults (131,132).

Figure 13.23. “Atrial Switch” catheterizations at Nationwide Children’s Hospital. Findings and procedures performed in 30 patients who underwent cardiac catheterization at Nationwide Children’s Hospital. All young adult patients had previously undergone a surgical “atrial switch” procedure for TGA.

Every study requires a full echocardiographic evaluation of the ASD. This should include assessment of the defect size in different planes (four-chamber view, short axis view, and SVC view), confirmation of normal pulmonary venous drainage, and evaluation of the AV valves for the presence of preexisting AV valve regurgitation. It is extremely important to evaluate all septal rims, including the superior rim with distance to pulmonary vein insertion and SVC, the inferior rim towards the AV valves, the anterior retroaortic rim, and the posterior-inferior rim that is in continuity with the IVC. It can at times be difficult to achieve a clear definition of the posterior-inferior rim toward the IVC with TEE, in which case ICE has a clear advantage. Although studies have documented that closure of ASDs even with multiple septal rim deficiency is feasible, this clearly increases demands of the operator’s technical skills (133,134).

Vascular access is usually obtained via the right femoral vein, placing an additional arterial monitoring cannula in the right femoral artery. Additional venous access from the right or left femoral veins may be necessary for ICE. In patients with bilateral occluded femoral veins, device deployment and delivery should usually be performed using transhepatic access, which may even provide better alignment of the device to the atrial septum (135). Internal jugular venous access is the least preferable access route and is unsuitable for device delivery in most patients. Heparin at a dose of 100 IU/kg is administered to maintain an activated clotting time of >200 seconds. A standard hemodynamic left and right heart catheter evaluation should be performed prior to device closure. This should include evaluation of pulmonary artery pressures, pulmonary vascular resistance, and estimation of the atrial level shunt. Angiographic evaluation of the ASD through an injection in the right upper pulmonary vein is not uniformly required but may aid as a roadmap for device orientation especially when

larger defects are being closed in smaller children. Angiography is usually performed using 35 degree LAO and cranial angulation. However, as the ASD’s position varies between patients, so does the best view to *en-face* profile the atrial septum. Therefore, tube angulations should be adjusted after initial angiography to achieve a better profile of the atrial septum. This view is then used throughout the device delivery and deployment process. In general, biplane views are not necessary to aid ASD device closure and, in fact, may hinder accessibility to the patient for the echocardiographer.

Even though the technical aspects of the treatment of adults with ASDs are not dissimilar to the treatment of smaller children (Fig. 13.27), the physiological effects of closing the intra-atrial communication have to be considered and evaluated very carefully, especially in older patients who have evidence of LV diastolic dysfunction. Closure of large intra-atrial communications in “unprepared” patients with LV diastolic dysfunction can lead to a significant increase in left atrial pressure due to the loss of “pop-off” via the atrial septum, with resulting pulmonary edema and ventilator dependency (136). The left atrial/wedge pressure should be evaluated at baseline as well as after test occlusion of the defect. In many patients, placing the device across the defect without release and then recording pulmonary artery wedge pressure via a second catheter eliminate the potential of the balloon size interfering with the obtained pressure tracing. While a small increase (<5 mm Hg) in left atrial pressures may be acceptable and reasonably well tolerated, an increase of left atrial pressure by a mean of 10 mm Hg or more is clearly prohibitive to occlusion of the septal defect (Fig. 13.24). Preferably, the treatment of any patient in whom these physiologic changes are expected, such as in older patients with a large ASD and systemic hypertension and/or LV dysfunction, should be optimized prior to engaging in any transcatheter procedure. This should include aggressive

diuretic therapy as well as afterload reducing agents. If a patient, despite appropriate pretreatment, still develops significant left atrial hypertension after test-occlusion, the placement of a fenestrated device may be necessary. Fenestrations within the device have been described, such as creating a communication through the ASO (AGA Medical Corporation, Golden Valley, MN), which can be created by direct puncture through the central connecting waist of the device using a larger sized dilator (137). Alternatively, if these fenestrations need to be maintained for a longer period of time, placement of a short endovascular stent through the device may be beneficial (138).

Technique of ASD Closure Using the AMPLATZER Septal Occluder

The left upper pulmonary vein is entered using either a wedge, multipurpose, or Judkins right coronary catheter and a pre-shaped, exchange length, extra stiff, j-tipped wire is advanced. Most operators would at this stage perform static “Doppler stop-flow” balloon sizing under echocardiographic guidance, using either an 18-, 24-, or 34-mm AGA sizing balloon (AGA Medical Corporation, Golden Valley, MN) or a NuMED sizing balloon (NuMED, Hopkinton, NY). It is extremely

Figure 13.24. Wedge pressure and ASD closure. Pulmonary arterial wedge pressure in a 70-year-old woman who was considered for transcatheter ASD closure. Top LV and wedge tracing before closure documenting a mean wedge pressure of 9 mm Hg. Bottom LV and wedge tracing after ASD occlusion with a 34-mm ASO deployed but not released, documenting an increased mean wedge pressure of 32 mm Hg and an increase in Left ventricular end-diastolic pressure (LVEDP). The device was subsequently recaptured and the ASD was left open.

important to expand the balloon until the atrial level shunt is just abolished. The dimensions are then recorded on echocardiography as well as on cine recording. However, unless a mild waist is visible, cine recordings can be misleading at times, as the angle of the atrial septum in relation to the sizing balloon may vary. One should clearly avoid any oversizing in an attempt to achieve a clear waist on the balloon, as oversizing of the device has been linked to the rare but serious complication of device erosion into the aortic root that has been described after ASD closure using the ASO (139). Many centers now completely avoid balloon sizing, especially in small children, and instead use an averaged maximum diameter taken from the three standard views to determine the appropriate device size. One would then add 25% to this diameter to determine the appropriate device size, which is often very similar to the ASD size determined when using color flow mapping. In patients with a deficient retroaortic rim where the two discs are expected to hug the aortic root on either side, the device size may have to be increased further. By subtracting 12 to 14 mm (depending on the device size), one can then estimate the maximum LA disc size that is suitable to close the defect without exceeding the septal length. Where balloon sizing is performed, the AGA sizing balloon may be advanced directly through the skin without the use of a hemostatic sheath, while the NuMED sizing balloon (NuMED, Hopkinton, MA) can pass through an 8 Fr sheath.

Once the device size has been determined, the appropriate delivery sheath is placed over the guidewire into the mouth of the left upper pulmonary vein. In addition to the standard AGA 45 degree delivery sheath, other long hemostatic sheaths can be used. The dilator and wire are gently removed and extreme care must be taken to avoid any inadvertent air entry into the sheath and left atrium at this stage. The device is then prepared for delivery, attaching either a Touhy-Borst adapter or the standard bleed-back valve that is supplied with the AGA delivery system to the loader. The delivery cable is passed through the assembly and the device, after being carefully inspected, is screwed onto the cable avoiding any force on the screwing mechanism. The device is then loaded under water seal and the whole assembly flushed with hand-warm saline. Once the loader is screwed onto the delivery sheath, the device is pushed forward under fluoroscopic guidance until the tip of the sheath is reached. The deployment is conducted under simultaneous echocardiographic and fluoroscopic guidance. The whole assembly is then pulled back until the tip of the delivery sheath exits the mouth of the pulmonary vein, at which stage the delivery sheath is pulled back while fixing the delivery cable to deploy the left atrial disc. Once the LA disc has been deployed, the position and orientation of the device are further evaluated on echocardiography, and while gently pulling towards the atrial septum, the alignment of device and septum are evaluated. At this stage, gentle rotation of the sheath may aid a better alignment. Once alignment appears suitable, the central connecting waist is deployed allowing "self-centering" and the whole assembly is pulled back against the atrial septum. In quick succession, this is followed by deployment of the right atrial disc once the connecting waist stents the defect itself. If the device pulls through the septum, the device is recaptured, the delivery sheath repositioned, and the deployment process started again. Various techniques have been used to achieve better alignment of the device, such as the use of specialized s-curved delivery sheaths (Hausdorf sheath, Cook, Bloomington, IN), deployment of the left atrial disc into the left or right upper pulmonary vein, use of a dilator advanced through additional venous access to prevent the device from pulling through the defect, and use of Judkins right coronary guide catheters for smaller devices (134,140,141). Before release, the device must be carefully evaluated by echocardiography. This should include assess-

ment for residual shunts around the device, obstruction of adjacent structures, as well as possible interference with the AV valves. The tension of the delivery cable will frequently distort device orientation and allow a moderate shunt between the separated discs. A careful push/pull action of the delivery cable should clearly demonstrate that the two discs are separate in all echocardiographic views as well as on fluoroscopy and the device should not easily be displaced through this very gentle push/pull maneuver. On occasions, right atrial angiography through the delivery sheath may be helpful to unmask inappropriate device position. Once the operator and the echocardiographer are satisfied with the device position, the device is released through counterclockwise rotation of the delivery cable using the supplied pin vice. The device usually reorients itself into a more appropriate position and therefore a final echocardiographic assessment is performed after release of the device (Fig. 13.25).

More challenging defects that require additional operator expertise are those with multifenestrated atrial septum, multiple larger ASDs, or those in very small children. Figure 13.26 demonstrates closure of multiple ASD using two ASO, while Figure 13.27 demonstrates closure of a multifenestrated atrial septum using the AMPLATZER Cribriform Septal Occluder. ASD closure in small children is particularly challenging, due to the small left atrial size and the relationship between device size and limited septal length in these patients (Fig. 13.28). In small children, especially when the weight is below 3 kg, the ICE catheter can be used as echocardiographic guidance in TEE position. Because of the reduced left atrial size, it is often necessary to pull up the TEE probe prior to device deployment, to avoid the device being tilted into an unfavorable position due to impingement of the TEE probe posteriorly (which frequently would let a device pull through the anterior retroaortic rim).

Results of ASD Closure Using the AMPLATZER Septal Occluder

Procedure or device-related complications after ASD device closure are extremely rare. Even though the risk of device embolization is low at about 0.5%, it can occur, especially when attempting to close very large defect with deficient rims in adults (142). Therefore, it is mandatory that any physician attempting to close ASDs be sufficiently trained and skilled in device retrieval, using, for example, a Gooseneck snare (Microvena Corporation, White Bear Lake, MN). The AMPLATZER Septal Occluder can usually be snared and recaptured into a sheath that is 2 Fr size larger than recommended by the manufacturer for that specific device, but attempts at snaring should only be performed within the atria, aorta, or pulmonary arteries. If a device has embolized into a ventricle, frequently manifesting itself with new and persisting ventricular arrhythmias, then surgical retrieval is usually indicated in order to avoid tricuspid or MV chordal injury. When a device is snared, one has to carefully manipulate the retrieval sheath to allow the screw of the device to readily advance into the sheath; otherwise capture of the device would not be possible (Fig. 13.29).

Early electrophysiological abnormalities are common within the first 24 hours after ASD device closure (143), but most of these resolve quickly and persistent rhythm or conduction disturbances 1 year after device closure are extremely rare (144). A release of nickel from the device with a peak at 1-month postimplantation has been described (145). However, its clinical significance is questionable and reports of clinically significant allergic reactions to nickel after device implantation are rare (146,147).

One of the most serious complications after ASD closure is erosion of the device into the aortic root, observed at an incidence of 0.1% (139). Even though the exact cause and risk factors for device erosion into the aortic root have not been

Figure 13.25. Closure of large secundum ASD. Closure of a large 32- to 34-mm secundum ASD using a 36-mm ASO. The device was deployed using a LUPV technique to achieve appropriate alignment with the atrial septum. **Top left:** Modified four-chamber view documenting larger ASD. **Top right:** Short axis view documenting large ASD with deficient retroaortic rim. **Middle left:** LUPV deployment technique. **Middle right:** Device postrelease. **Bottom left and right:** Short axis view without and with color flow mapping after release, documenting excellent device position and no significant residual shunt.

identified, oversizing has been a concern in these patients (139). Most cases of erosion (Fig. 13.30) present in adults within a few days of the procedure with symptoms of chest pain and echocardiographic evidence of a pericardial effusion. However, device erosion can occur with more subtle symptoms several months after the procedure and may only be diagnosed after

fatal erosion into the aortic root has occurred. While there is no valid tool available that identifies device erosion at an early stage, symptoms of chest pain or the presence of a pericardial effusion should alert the cardiologist to this potentially fatal complication. A multislice volume-rendered CT scan with 3D reconstruction allows evaluation of the device from all

Figure 13.26. Closure of multiple ASDs. Closure of two secundum ASDs in a 59-year-old-man using 20- and 13-mm ASO. **Top:** Two devices deployed but not released with the larger device being “sandwiched” within the smaller device. **Bottom:** Both devices after release.

views and as such can potentially demonstrate the relationship between device, atrial wall, and aortic root (Fig. 13.31).

Closure rates are excellent with residual shunts being <5% at 1-year follow-up (32,134,148,149). The RV diastolic diameter tends to decrease after ASD closure suggesting some degree of remodeling when the exposure to volume loading is eliminated (150).

While technically challenging, ASD closure in small children can be successfully performed. Holzer and colleagues reported on 26 patients with a weight below 10 kg (2.4 to 10 kg) in whom ASD closure was attempted. Rim deficiencies were present in 31% of patients and the overall procedural

success was 95%, with one unsuccessful procedure being related to a deficiency of the inferior rim.

ASD Closure Using the Helex Septal Occluder

Delivery of the Helex Septal Occluder is slightly more challenging than the ASO. The deployment technique has been previously described in various articles (151–154). Jones et al. (154) reported on the results of 135 patients who were enrolled in an FDA phase II multicenter trial. Device delivery was successful in 119/135 (88%) patients. The incidence of device embolization requiring catheter retrieval was 1.7%. At 12-month follow-up, 73% of defects were completely occluded, 25% had a clinically insignificant residual shunt, while 2% had a clinically significant residual shunt. The HELEX Septal Occluder appears to be more suitable for smaller defects, rather than large ones. In contrast to the ASO, balloon sizing is essential and a device at least twice the size of the stretched diameter (stop-flow) should be used. Serious complications such as erosions into the aortic root that have been described with the AMPLATZER devices have not been observed with the HELEX Septal Occluder thus far, which is an important advantage when considering the use of the HELEX Septal Occluder for smaller ASD and PFO.

ASD Closure Using the CardioSEAL and STARFlex Devices

Technical details of ASD closure using these devices have been described elsewhere (25). In 2000, Carminati et al. (155) reported on the European multicenter experience of using the CardioSEAL and STARFlex double umbrella devices to close intra-atrial communications in 334 patients with a mean age of 12 years. Implantation was achieved in 97% of patients, with early device embolization being seen in 4% of procedures, most of which required surgical removal of the device. Residual shunting has been observed more frequently when compared to the ASO. Immediately after the procedure, 41% of patients had a detectable residual shunt that decreased gradually to 21% at 12-month follow-up. However, when excluding trivial leaks, the rate of complete closure was as high as 93% at 1-year follow-up. Two patients required late explantation of the device, one due to malposition and one due to late embolization. Fractures of the device arms were seen in 6% of patients, not associated with clinically significant adverse events. Device erosions into adjacent structures were not observed and no patient died as a result of the device implantation. Unfortunately, only defects ≤20 mm can be reliably closed using these devices, a significant limitation for patients with larger defects.

Some Comments on PFO Closure

Device closure of PFO using the ASO is very similar to ASD closure and technically fairly straightforward in most patients. Balloon sizing may avoid choosing a device that is too large for the individual patient, even though most ASO will fall in the range from 12 to 18 mm. The not-yet approved AMPLATZER PFO Occluder (AGA Medical Corporation, Golden Valley, MN) is specifically helpful for the longer tunnel-like PFO and also aids in the stabilization of an associated septal aneurysm. It is currently investigated in a Randomized Evaluation of Recurrent Stroke Comparing PFO Closure to Established Current Standard of Care Treatment (RESPECT). The presence of an atrial level right-to-left shunt should be evaluated before and after PFO closure using either bubble contrast echocardiography or transcranial Doppler. The recently approved AMPLATZER Cribriform Septal Occluder (AGA Medical Corporation, Golden Valley, MN) may have some use in transcatheter closure of PFO.

Figure 13.27. Closure of multifenestrated ASD. Multifenestrated atrial septum with at least three separate shunts on echo color flow mapping. **Top:** Multifenestrated septum before device placement associated with atrial septal aneurysm. **Bottom:** Atrial septum after device placement—note the flat appearance of the device and septum without a significant central waist.

The HELEX Septal Occluder has also been used frequently in Europe to occlude PFO. Sievert et al. (156) reported their experience of 33 patients and identified residual shunts at 6-month follow-up in 5.5% of patients, without any procedure or device-related complications. No recurrent neurological event was observed in these patients during a mean follow-up of 12 months (156). Within the US, the use of the HELEX Septal Occluder to close PFO in patients with cryptogenic stroke as compared to standard therapy with Aspirin, is presently being evaluated in the REDUCE trial. Similar to the ASO and the HELEX Septal Occluder, the (no longer available) STARFlex Occluder was evaluated for the treatment of PFO and stroke (CLOSURE I trial) (24,25).

Transcatheter Closure of Fontan Fenestrations

Transcatheter closure of fenestrations created surgically during the completion of a Fontan is usually considered in patients who have transcutaneous oxygen saturations equal to or below 90% after completion of Fontan. While the CardioSEAL ASD occlusion device had standard use approval under the FDA for occlusion of these defects, many other approved

devices have been used on an off-label basis and the most commonly used devices for this indication are presently the smaller varieties of the ASO (Fig. 13.32) (157,158). While in general, these defects are closed in a similar fashion to secundum ASDs, there are a few important considerations. Balloon test occlusion of the fenestration should be undertaken for 10 to 15 minutes, allowing for careful evaluation of right atrial pressures, systemic pressure, oxygen, and cardiac index. If test occlusion is well tolerated, the defect can be closed using a variety of approaches. Even though the jugular venous approach is unsuitable for occlusion of ASDs, small surgically created fenestrations are usually more amenable to this approach, as the small size of the defect allows a much harder pulling force to be exerted that overcomes the disadvantages otherwise encountered through inappropriate alignment. The location of surgical fenestrations may be close to the tricuspid valve and therefore careful echocardiographic assessment is necessary to avoid the device dropping into the tricuspid apparatus. Ideally, the left atrial disc should be deployed close to the fenestration. In many cases, the smallest device size of an ASO (4 mm) is sufficient for occlusion. In patients with extracardiac Fontan circulation and a short tubular connection to the atrial mass, the ADO may be more suitable to close this fenestration (159).

Figure 13.28. ASD closure in infancy. An 8 months (6.5 kg) ex-premature ventilator-dependent infant with bronchopulmonary dysplasia and a moderate (9 mm, unstretched) secundum ASD with deficient retroaortic rim (**Top left**). **Top right**: Standard deployment technique was unsuccessful in aligning the device with the atrial septum, **Bottom left**: Left upper pulmonary venous deployment technique. **Bottom right**: Device alignment and position after release (11-mm ASO). Patient was subsequently weaned off the ventilator.

Transcatheter Closure of Ventricular Septal Defects

Background and History

Transcatheter closure of muscular VSDs was first attempted on a compassionate basis using the larger Rashkind PDA occluding device (7). In 1988, Lock et al. (7) reported on a series of six patients in whom muscular VSDs—including postinfarct VSDs—were closed using the Rashkind device. Although the device and technique were successful in some cases, the device frequently was too small and resulted in significant residual leaks or actual embolization of the device. Some shortcomings of the Rashkind device were overcome by the design and larger sizes of the Clamshell device, making this a useful technique for some otherwise difficult to treat VSDs (160). Its successor, the Cardio-SEAL, had been used to close a variety of muscular VSDs (161). However, the most commonly used approved device for closure of muscular VSD is the AMPLATZER Muscular VSD Occluder.

Other devices have been used “off-label” to close muscular as well as perimembranous (39) VSDs, including the buttoned device (162), detachable coils (163–165), and the ASO (166). However, these devices as well as the approved Cardio-SEAL device were designed for different indications and as such are not generally adapted to suit the very different anatomical and morphological parameters (such as septal thickness) that are encountered with muscular VSDs.

It was not until 1999 when Thanopoulos first reported on the use of a custom-made device for closure of muscular VSDs (37). Results of the AMPLATZER Muscular VSD Occluder have been encouraging (167–170). In contrast to muscular

VSDs, perimembranous defects pose much higher demands on device design due to their proximity to the aortic valve, and early trials with “off-label” use of the Rashkind double umbrella were quickly abandoned (39). In 2002, Hijazi et al. (41) first reported on the use of a custom-designed device to close perimembranous VSDs and phase I trials investigating the AMPLATZER Membranous VSD Occluder were conducted in the United States (171) (Fig. 13.33). However, a serious and worrisome complication after implantation of the AMPLATZER Membranous VSD Occluder is the development of CHB. Its incidence in reported studies ranged from 2% to 3% (171,172). More recent reports of even higher incidence of CHB have appeared in several international registries, up to 4% to 5%. Even though heart block may develop during the procedure itself (173), it has been reported to occur at any time from within a few days to within a few months after an otherwise uncomplicated procedure (172,174). So far, no specific factors have been identified that allow prediction of these serious events. Because of the high reported incidence of AV block at present, the device is presently not approved for closure of perimembranous VSDs (and therefore the technique is not described in this section). Device modifications that may allow a reduction in external forces exposed onto the conduction system are presently being evaluated.

Technique of Muscular VSD Closure Using the AMPLATZER Muscular VSD Occluder

The principle technique for device closure of muscular as well as perimembranous VSDs is similar, with the device usually being deployed from an antegrade approach. For apical

Figure 13.29. ASO device retrieval. A 29-year-old man who underwent ASD closure using a 20-mm ASO. The following day the device was found to have embolized to the DAO (A). The device was snared using a Gooseneck snare (B) and subsequently the screw aligned with the retrieval sheath (C). The device was recaptured into the sheath (D).

and mid muscular locations of the defects, the device delivery usually is from the superior vena cava (SVC); defects in the anterior muscular septum generally are approached from the IVC. This combination of circumstances results in a complex delivery technique requiring an arterial-venous guidewire “rail” passing from the arterial approach to the left ventricle, through the defect into the right ventricle, and ultimately being exteriorized either via femoral or internal jugular vein.

The procedure is performed using continuous TEE. After an initial hemodynamic evaluation and LV angiography, the VSD is usually crossed from the LV using a Judkins right coronary catheter and a 0.035-inch exchange length angled glide wire. The wire is snared using an Amplatz Gooseneck snare (Microvena Corporation, White Bear Lake, MN) either in SVC or in pulmonary arteries and exteriorized via femoral vein or internal jugular vein, thereby establishing a “rail” that can then be used to advance the appropriate diameter long delivery sheath through the defect and into the left ventricle. Device delivery is similar to that of the ASO for ASD closure. However, especially the closure of posterior-inferior defects is frequently complicated by delivery sheath kinking. Because of the complexity of the procedure, transcatheter muscular VSD closure should be limited to a few centers that have the

necessary interventional expertise. A perventricular approach described later in this chapter is preferred over a percutaneous approach for small infants, due to the higher incidence of adverse events associated with percutaneous device delivery in that population (175).

Results of Transcatheter Closure of Muscular VSDs

An early multicenter US experience of 75 patients was reported by Holzer et al. (170) in 2004. Procedure and device-related complications occurred in up to 39% of patients, almost a quarter of which were classified as major. The mortality in this early multicenter trial was 2.6%. Weight below 10 kg has been identified as a significant risk factor for adverse events. Closure rates were 40% immediately after device deployment, and increased further to 92% at 12-month follow-up (170). In 2005, Thanopoulos and Rigby (169) reported one case of subsequent development of CHB 1 year after device implantation in a series of 30 patients with a median follow-up of 2.2 years. Closure rates as high as 93% were described. Reports suggest that the relatively high rate of procedure-related complications in infants might be reduced through a perventricular approach through the beating heart without

Figure 13.30. ASO erosion. Pathology specimen after erosion of the AMPLATZER Septal Occluder through the left atrial wall into the aorta is shown here. The ASO is seen “endothelialized” with the edge of the device against the LA free wall (top). A probe is placed through the aortic erosion adjacent to the erosion seen in the roof of the LA (bottom).

need for cardiopulmonary bypass (168,176). It has been suggested that when the advantages and disadvantages of the surgical approach to muscular ventricular defects are weighed against the risks and difficulties of the catheterization technique, the transcatheter route may be an effective alternative in selected patients with a decreased morbidity.

Postinfarction muscular VSDs require very specific considerations. In 2004, Holzer et al. (177) reported on 18 patients in whom occlusion of a postinfarct VSD was attempted using the AMPLATZER Muscular VSD (postmyocardial infarction) Occluder. A device was successfully placed in 89% of procedures, with early 30-day mortality being about 28%. On follow-up, two patients underwent recatheterization to close a residual VSD. At a median follow-up of 332 days, 20% of patients had complete closure, 60% had a small residual shunt, and a further 20% had a moderate residual shunt (177). Even though results of device closure of postmyocardial infarction VSD are poor, they have to be interpreted in context with the background of early surgical mortality being as high as 27% to 46%, with the mortality in untreated patients exceeding 90% (178–180). Unfortunately, so far, the device design for postinfarction VSD remains suboptimal, both in sizes available and device configuration. Residual shunts are not uncommon.

It is possible that the addition of further Dacron fabric to the device may help. From our own experience, we have found that the maximum available device size of 24 mm is frequently insufficient to occlude larger postinfarct VSDs. Whether a per-ventricular approach may aid in reducing the perioperative mortality has not been evaluated.

TRANSCATHETER OCCLUSION OF PATENT DUCTUS ARTERIOSUS

At present, the most commonly used device to close medium or larger sized arterial ducts in the United States is the ADO which was introduced in 1997 (49). It presently is the only device that has been FDA approved specifically for closure of the patent arterial duct. However, many small PDAs are still being occluded using a variety of coils. The Nit-Occlud device is awaiting FDA approval, while the ADO II is presently undergoing phase II clinical trials in the United States.

Coil occlusion of the arterial duct can be performed using either an antegrade or retrograde approach. For very small PDA, a retrograde arterial approach is usually sufficient. Before crossing the patent arterial duct, an aortogram is performed just at the origin of the PDA using standard lateral projection as well as 30-degree right anterior oblique projection of the AP tube. Measurements of the pulmonary arterial end, the aortic end, and the total length of the arterial duct and its midportion are made. According to a classification by Krichenko et al. (181), the arterial duct can be described angiographically as classically cone-shaped (type A), short with a narrow aortic end (type B), tubular (type C), having multiple constrictions (type D), or elongated conical with a distant constriction (type E). Hemodynamic evaluation is performed prior to angiography, including assessment for any pressure gradient across the aortic arch as well as a full right heart catheterization in cases where an antegrade ductal closure is anticipated. Care should be taken to avoid inadvertently entering the duct before angiographic evaluation can be completed, as that may trigger ductal spasm that may make it impossible to obtain accurate measurements and could in the worst-case lead to the patient having to be rescheduled for a repeat procedure (Fig. 13.34). The antegrade approach has the advantage of allowing angiographic evaluation before the coil is completely deployed but both techniques are equally used and suitable.

A coil usually twice the size of the pulmonary end of the duct is chosen and coils are deployed in a way to allow placement of about one loop being distal to the pulmonary arterial end, while the remainders of the loops are placed in the ductal ampulla. The length of the coil is usually three to five loops and depends on the length of the aortic ampulla. Delivery of Flipper or Jackson coils (or the newer MRye Flipper coils) is technically fairly easy and the controlled release mechanism allows an extra safety margin to prevent inadvertent coil embolization. If the coil position appears suboptimal, the coil can be recaptured and redeployed into a more appropriate position. However, Flipper coils with their reduced amount of filament are not always suitable to close especially medium sized PDAs. Therefore, techniques have been developed that allow delivery of the standard Gianturco coils in a more controlled fashion, such as the use of a snare (182) or biptome (183) to hold onto the coil, the use of a tightened catheter tip (184), or the use of a balloon (185) to tamp the coil within the ductus during deployment. Even without these aids, closure of many arterial ducts is feasible using just the standard Gianturco coils, as has been demonstrated through many successful procedures, performed before any other devices became available. If a residual shunt is present after placement of a coil, attempts should be made to place an additional coil. Residual

Figure 13.31. ASO relation to aortic root. Multislice volume rendered CT scan demonstrating the relation of the ASO to the aortic root in a patient who developed chest pain after transcatheter ASD closure. Arrowheads point to the device. **Left:** On-face view of the ASO in relation to the aorta. **Right:** Profile view of the ASO in relation to the aorta (Images provided by Stephen Cook, MD).

shunts not only fail to abolish the risk of bacterial endocarditis, but in addition are associated with an increased risk of intravascular hemolysis (186). Sufficient time (10 to 15 minutes) should be given to allow clotting to occur before attempting to place an additional coil, which is usually placed using a retrograde approach. The duct is carefully crossed using, for example, a 0.018 V18 wire or a 0.035 angled glide wire. A soft 4 Fr catheter, such as a glide catheter, should then be tracked over the wire and advanced carefully across the PDA before placing an additional coil that is usually of smaller diameter than the one that was originally placed. Before introduction of the ADO, many moderate- to large-sized PDAs were occluded using multiple coils in this fashion (187).

The technique of closing the arterial duct using the ADO has been described in detail by Masura et al. (49). After hemodynamic and angiographic evaluation, the PDA is crossed antegrade and a 0.035-inch exchange length wire is advanced into the DAO. An appropriate delivery sheath is advanced over the wire with the tip positioned in the lower DAO. The wire is then removed and the device is loaded in a way similar to the ASO. The device size is chosen so that the pulmonary end of the skirt is about 2 mm larger than the size of the narrowest PA portion of the arterial duct. In a typical type A PDA with a 3- to 4-mm pulmonary arterial end, one would therefore choose an 8/6-mm ADO. However, in very small patients, the device size is chosen to be frequently on the smaller side, while very large PDA may require a device notably larger than just 2 mm above the narrowest PDA segment. The device is advanced until it reaches the tip of the delivery sheath. At this point, the whole assembly is gradually withdrawn in small increments. One should begin to deploy the retention disc when a position just in mid-portion of the DAO opposite to the PDA insertion is reached. It is important to use the angiographic recordings as a roadmap when deploying the device, with specifically the anterior end of the trachea and its relation to the PDA as a reference point. Once the retention disc is deployed, the whole assembly is withdrawn into the mouth of the aortic ductal ampulla, at which point the skirt is deployed while fixing the delivery cable and retracting the sheath. In type E PDA, tubular type C PDA, or elongated arterial ducts with a typical cone

shape, it may be necessary to withdraw (or begin to deploy) the retention disc inside the PDA. Once the device is deployed, a Pigtail catheter is advanced and positioned opposite the PDA in the DAO. Aortography is then performed, carefully evaluating for the presence of any residual shunt around the device. One can repeat the aortogram after 10 to 15 minutes to allow clotting to occur if required. Without any residual shunt, the device can be released and its position should again be evaluated through a final angiogram (Fig. 13.35). Pressure recordings in the ascending and DAO, as well as LPA and MPA should be obtained before and after device deployment. Even though the device is only recommended for use in infants above 5 kg, it is our experience that the ease with which the device can be recaptured if the position is not satisfactory should allow an attempt at PDA occlusion in any duct beyond the neonatal period, even if the patient's weight is below 5 kg (Fig. 13.36). The key to successful deployment in small patients is not necessarily the size of the PDA, but more so its length.

As an alternative to deployment of the ADO, the ADO II can be deployed using either an antegrade or a retrograde approach due to the symmetric shape of the device. The deployment technique is otherwise very similar to the ADO, with one disc being deployed at the aortic ampulla, the central portion within the PDA, and the more proximal disc deployed at pulmonary arterial opening of the duct (antegrade approach, Fig. 13.37). For some type C, type D, and type E PDAs, the AMPLATZER Vascular Plug II can be used successfully, again using usually an antegrade approach (Fig. 13.38) (56).

Results of PDA Closure

In 1999, Patel et al. (188) reported their experience of PDA coil occlusion in 149 patients. Out of 146 patients who had coils implanted, the rate of immediate complete closure was 97%. In three of four patients with a residual shunt, complete occlusion was achieved during a second transcatheter procedure, while the residual shunt spontaneously resolved in another. The study documented zero mortality and very low morbidity. Coil migration during the procedure was seen in six patients (4%); four were successfully retrieved. Recanalization

Figure 13.32. Closure of Fontan Fenestration. An 18-year-old girl with heterotaxy and an extracardiac Fontan (hepatic confluence to LPA). Fenestration occluded using 5-mm ASO. Top: Before occlusion. Bottom: After occlusion.

or delayed coil migration was not observed during a median follow-up period of 3 years. The risk of inadvertent coil embolization when attempting to close large PDA with a PA diameter in excess of 4 mm, has been documented to be as high as 16% (187). However, most published data about PDA coil occlusion preceded the introduction of the controlled release Flipper coil as well as the introduction of the ADO, which is now available for moderate- or large-sized PDA. As such, the rate of inadvertent embolization can today be expected to be <1%, if full use is made of all available devices and techniques.

Pass et al. (189) reported the results of a multicenter US trial evaluating the ADO, which enrolled 484 patients with a median age of 1.8 years between 1999 and 2002. The ADO was successfully implanted in 99% of suitable patients. Occlusion rates increased from 76% immediately at the end of the procedure to 89% at day one postprocedure and further to 99.7% at 1-year follow-up. For the ADO II, Saliba et al. (190) reported closure rates 94% at 24 hours.

Major complications were reported in 2.3% of patients while the incidence of minor adverse events was about 4.8%. Partial occlusion of the LPA was seen in two patients. However, no case of significant aortic obstruction was identified. Device embolization occurred in two patients, necessitating surgical retrieval in one. Vascular complications or blood loss requiring transfusion were reported in 18 patients and one patient died of overwhelming sepsis 5 months after the procedure. Embolized ADOs are more difficult to retrieve compared to other AMPLATZER devices, because of the recess of the microscrew into the device. Therefore, devices are usually retrieved using at least a 4 Fr larger delivery sheath allowing collapse of a device that has been snared circumferentially. Ducts of atypical (non-type A) morphology are technically more challenging and may require variations in the type and positioning of devices used.

Even though the AMPLATZER Vascular Plug has been used to occlude persistent arterial ducts (55,191), caution has to be applied for this indication, because the lack of Dacron fabric in these devices may prevent complete occlusion in moderate-sized high-flow PDA, as was demonstrated in a patient with a type C PDA (192,193). However, this does not appear to be a problem when using the AMPLATZER Vascular Plug II, with its triple-layered Nitinol mesh and improved occlusive properties (56).

In 2003, Chisolm and colleagues reported on 19 patients in whom a Nit-Occlud was implanted as part of the phase II US clinical trial. Devices used were either Nit-Occlud Flex or Nit-Occlud Medium of various sizes. At 24 hours, 17/19 (89%) had no residual flow, while there was trivial residual flow in one and a small degree of residual flow in another patient. Procedural complications or device embolizations were not observed (53). In 2005, Celiker et al. (54) reported a closure rate up of 93% after 6 months.

CLOSURE OF OTHER PERSISTENT OR ABNORMAL VASCULAR COMMUNICATIONS

Techniques for embolization of abnormal or persistent arterial or arteriovenous vascular structures have been available for more than 30 years. Embolization techniques were developed and perfected primarily by vascular radiologists working in the abdominal viscera, gastrointestinal areas, and central nervous system, particularly in “end artery” vessels. Many materials and devices, including the patient’s own clotted blood, Gelfoam, colloidal plugs, “glues,” detachable balloons, and coil occlusion devices have been used for these peripheral occlusions.

Gianturco (Cook, Inc.) coils, and their MRI compatible successor the MRye coils, are the most commonly used occlusion

Figure 13.33. Closure of Perimembranous VSD. Closure of a perimembranous VSD. **Left:** Before closure. **Right:** After closure.

devices for patients with congenital cardiac defects. These coils are made of spring wire with polyester fibers enmeshed in the coils. They are available in several sizes and multiple diameters and lengths. The coil is introduced into the delivery catheter through a straight metal “loader” as a straight wire. When it is delivered by extrusion out of distal end of the catheter, it coils

like a small “pigtail.” Once delivery with this particular coil has been started, there is no way of withdrawing the coil back into the catheter. The Gianturco coil occludes the vessel by creation of a mass of fabric and wire where a thrombus forms. The coil occlusion device usually is delivered into a vessel with a discrete distal narrowing, where it will fix in place and not migrate further through the vessel. Often, several coils are placed in a single vessel to achieve complete occlusion. In the absence of a distal narrowing or some other type of device for fixation, coils are generally only usable in tubular structures with a distended diameter up to 7 to 8 mm. For larger vessels or vessels without an area of discrete stenosis, coils can be used in conjunction with other intravascular occlusion devices to complete the occlusion of the vessel. Other devices that are available to occlude slightly larger vascular structures include the AMPLATZER Vascular Plug (Fig. 13.36), The AMPLATZER Plug II (Fig. 13.37), the ADO, and the GGVOD.

Many abnormal collateral vessels or persistent surgically created systemic to pulmonary artery shunts are associated with more complex lesions. These vessels should be occluded when systemic flow competes with normal pulmonary flow, particularly after the major defect is corrected. These communications were traditionally delivered during the corrective surgical procedure or as a separate procedure. Other lesions in which these devices may be useful are AV fistulae, including systemic, coronary–cameral, and peripheral as well as pulmonary AV fistulae. In these lesions, it is critical to identify the stenotic or “end” vessel into which the device can be fixed in order to reduce the dangers of migration to a vital structure. A variety of other persistent and abnormal vascular communications can be occluded with the available devices, including a left SVC to the left atrium, systemic to pulmonary artery shunts in postoperative tetralogy of Fallot or PA patients, persistent systemic venous to atrial connections after the Fontan or Glenn procedures (Fig. 13.39), and others.

As early as 1989, Perry et al. (45) reported on their experience of occluding 77 vessels in 54 patients using Gianturco coils. The rates of total or subtotal occlusion immediately during the procedure were as high as 95%. Complications included six cases of inadvertent embolization into the pulmonary or systemic circulation, half of which were retrieved using transcatheter techniques and half of which were left without symptoms. This study, however, represents early results. Current practice is to continue to place multiple coils until complete or near complete occlusion of a vessel is confirmed angiographically, and detachable Flipper coils are usually preferred for any attempted occlusion that may be associated with a slightly higher risk of inadvertent coil embolization.

Hill et al. (192) reported a multicenter experience of 52 patients in whom 84 vessels were occluded using 89 AMPLATZER Vascular Plugs. The most commonly occluded

Figure 13.34. Ductal Spasm. PDA in spasm after catheter manipulation (A) and after waiting for 30 minutes for spasm to resolve (B).

vessels included 45 aortopulmonary or venovenous collaterals, 28 pulmonary AVMs, 7 transhepatic tracts, and 4 shunts. Complete occlusion of the vascular structure was accomplished within 10 minutes in 94% of implanted devices. More than one vascular plug was required for five vascular structures. Two vascular plugs were electively removed due to residual shunts.

RETRIEVAL OF FOREIGN BODIES

With the proliferation of various types of chronic parenteral therapy, central line monitoring, chronic indwelling intravenous chemotherapeutic devices, and now the catheter-delivered therapeutic devices, the nonsurgical removal of embolized for-

Figure 13.36. PDA closure in a formerly premature neonate. A 3 months ex-premature infant with BPD who remained CPAP dependent. Catheterization documented a moderate tubular type C PDA, measuring approximately 2 to 2.5 mm throughout its length (**top**) with a $Q_p:Q_s$ of 2.5:1. PDA was successfully closed with a 4-mm Vascular Plug II. **Middle:** Aortogram with device still attached to delivery cable. **Bottom:** Aortogram after release of the device.

eign bodies from the heart or great vessels has become a more frequent challenge for the interventional cardiologist. The pediatric interventional cardiologist, who is more familiar with complex intracardiac anatomy and with the routine use of biplane fluoroscopy, is generally best qualified to perform these procedures, regardless of the patient's age. Fortunately, and thanks mostly to urologists, a variety of catheter devices is available for the grabbing, snaring, looping, or lassoing of any type of debris that work its way into the vascular system and must be available in any interventional catheterization laboratory.

Most of embolized materials end up in the pulmonary artery branches. Retrieval involves the delivery of a large sheath (8 to 15 Fr, depending on size and shape of the foreign body

Figure 13.38. PDA closure with plug II. A 16-month-old male infant with a moderate tubular (type C) PDA (top) and a $Q_p:Q_s$ of 2.5:1 (Middle); aortogram showing a 6-mm vascular plug II deployed and (bottom); aortogram after release of the device.

that is to be retrieved) into the specific branch pulmonary artery just proximal to the foreign body. The specific type of retrieval catheter used is determined by the size of the patient, the type of foreign body, and exactly how and where the foreign body is situated within the vascular system. Then, either directly through the sheath or through a catheter delivered through the sheath, the particular retrieval device is advanced to the foreign body and manipulated to grasp it. Once firmly grasped, the foreign material is withdrawn into the large sheath and out of the body through the sheath. With the use of the large, long sheaths with these retrieval devices, it is usually no longer necessary to perform a venous cutdown even for the final removal of the foreign body from the vessel or skin entry site.

One of the most common iatrogenic foreign bodies retrieved by the congenital interventional cardiologist is an embolized ASO, which is described above (Fig. 13.29).

MANAGEMENT OF PERIPROSTHETIC LEAKS

Periprosthetic leaks are notoriously difficult to treat. A variety of devices has been used successfully in selected patients, by either an antegrade or a retrograde approach (194–201). However, the crescent-shaped form of many of these defects combined with the biophysical characteristics of the adjacent prosthetic valves does not lend themselves for the use of any of the currently available transcatheter devices, and complications such as impairment of the prosthetic valve or wire entrapment have been documented (202,203). Development efforts are presently underway to design a custom-made device specifically designed for the closure of periprosthetic leaks, which will hopefully improve upon the currently available devices that have been used for these indications.

TRANSCATHETER PULMONARY VALVE REPLACEMENT

The groundbreaking work by Dr. Phillip Bonhoeffer has initiated one of the most exciting developments in transcatheter therapy of recent years. Patients with significant conduit dysfunction have so far required surgical (re)placement of a valved conduit between the right ventricle and pulmonary arteries. The longevity of these conduits has been limited, necessitating further conduit replacements every 5 to 15 years for recurrent

conduit stenosis or new or recurrent valve insufficiency. The prospect of frequent open-heart procedures is very undesirable in this group of patients, who usually already have undergone a series of cardiac surgical procedures, each adding further potential insults to global left and RV function. In addition, because of scarring, these operations are potentially very difficult to perform. As such, a less-invasive procedure that would further extend the need for surgical conduit replacement was most desirable.

In 2000, Bonhoeffer et al. (9) reported on the first human implantation of a stent-mounted valve into an RV-PA conduit in a 12-year-old boy. The technique has been modified since and until now more than 1,000 patients have received a transcatheter-stented valve in the pulmonary position (204). The Melody valve utilizes a bovine jugular venous valve that is preserved in glutaraldehyde and mounted within a 28-mm-long CP stent. The valve is ideally implanted into a preexisting RV-PA conduit, preferably with a degree of associated stenosis, and expanded up to a diameter of 18, 20, or 22 mm. At the present time, in the United States, the valve is not approved for use in patients with a native pulmonary valve, a patched RVOT, or positions outside the RVOT such as the tricuspid valve.

Implantation of the Melody valve requires careful pre-procedural planning and patient selection, closely involving the adult congenital team. Patients with significant conduit stenosis pose different procedural challenges than those with predominant valve insufficiency. Once a patient has been identified to require pulmonary valve or conduit replacement, he/she should be reviewed by the interventional team to assess whether he/she would be a suitable candidate for the Melody valve. Patients with very large nonstenotic conduits with diameters of 25 mm or more are generally questionable candidates. Using the 22-mm Ensemble delivery system, the outer diameter of the Melody valve is approximately 24 mm, and therefore any inner diameter of a conduit larger than this would be insufficient to securely anchor the Melody valve. While the valve could theoretically be mounted on a 24-mm BiB balloon, this technique is more challenging and is not the standard technique approved in the United States. When deciding about the size of a conduit, one has to bear in mind that conduits that house a bioprosthetic valve, such as the Hancock conduit, usually have an inner diameter at the valve ring of about 2 mm less than the nominal size of the conduit. Once a patient has been found to be a suitable candidate, a careful diagnostic and hemodynamic evaluation is performed within the catheterization laboratory. Particular attention has to be paid to the location of the coronary arteries in relation to the desired implantation site of

the Melody valve (Fig. 13.40). For this purpose, a balloon of similar size as the intended Melody valve is advanced over a stiff guidewire into pulmonary position and inflated, while a simultaneous aortogram is obtained. To allow visualization of the coronary arteries through the balloon, very diluted contrast (20%) is used. If any doubt exists about the coronary arteries, selective coronary angiograms can be performed. In addition to lateral projection, caudal and LAO projection usually profile the left coronary artery very well in relation to the balloon position. In addition to evaluating the coronary anatomy, pretreatment of a stenotic right ventricle to pulmonary artery (RVPA) conduit may be required. As stent fracture is one of the most common complications seen after Melody valve implantation, operators may want to eliminate the majority of conduit narrowing prior to implantation of the Melody valve, in order to reduce the radial force on the valve. For this purpose, balloon sizing is undertaken. If, at low pressure, the waist seen in the balloon is 80% or less than that of the desired diameter, a smaller balloon is used. This gradual approach may limit

the injury that is being caused to the conduit through balloon angioplasty. Prestenting the RVPA conduit has been favored by many operators, implanting sometimes as many as four to five stents to give the conduit enough radial strength to reduce the risk of subsequent stress fractures of the implanted Melody valve (Figs. 13.41 and 13.42). Furthermore, if a Melody valve is implanted without eliminating the stenosis sufficiently through prestenting, very little can be done subsequently if the Melody valve shows some recoil as a response to external radial forces. Once the “landing zone” for the Melody valve has been prepared in such a fashion, a Lunderquist extra stiff wire (Cook, Bloomington, IN) is placed in the most appropriately sized branch pulmonary artery, which then facilitates advancement of the Ensemble delivery system and eventually deployment of the Melody valve. The crimping process, predilation of the entry site, and advancement of the Melody valve have been described elsewhere and are therefore not described in detail in this section (Fig. 13.43). ICE is a useful tool to evaluate valve function after implantation (Fig. 13.44).

Figure 13.40. Melody valve and coronary compression. A patient with tetralogy of Fallot and the LAD coronary artery arising from the RCA is evaluated for Melody TPV implant. A selective LAD injection in steep caudal angulation and a lateral view (**top**) is shown. A guidewire has been placed through the RVOT into the LPA. There is no observed obstruction to coronary flow. However, with inflation of the balloon in the RV-PA homograft, there is clear compression of the LAD branch (**bottom**). Implant of any bare metal stent or the Melody TPV would result in coronary ischemia. Therefore, this patient was referred for surgical pulmonary valve replacement.

Figure 13.41. Melody valve stent fracture. A patient underwent implantation of the transcatheter Melody valve within a homograft. After balloon compliance testing, the Melody TPV is implanted in a homograft. After 1 year, the patient's systolic gradient increased and fluoroscopic examination of the valve demonstrated multiple fractures and loss of stent integrity (**bottom**). The patient was successfully treated with a new valve after two bare metal stents were placed to reinforce the original valve.

Figure 13.42. Melody valve and pretesting. There is increasing evidence that pretesting conduits using bare metal stents where a noncompliant surrounding environment exists may reduce the incidence of Melody TPV fatigue fractures and prolong the life span of the valve. In this very complicated patient who had multiple surgeries as well as an ICD, an RV angiogram demonstrates the narrowed conduit (**top left**). Four Palmaz XL stents were implanted until recoil of the stent was not observed and the PA angiogram demonstrated wide open PR (**top right**). The Melody TPV was then implanted within the bare metal stents (**bottom left**) and a repeat PA angiogram showed no residual stenosis or regurgitation (**bottom right**).

Figure 13.43. Procedural stages of Melody valve implant. The following images demonstrate the procedural steps for Melody TPV implant in a patient with a degenerating bioprosthetic pulmonary valve. A PA angiogram shows combined pulmonary valve stenosis and regurgitation (A). Balloon compliance testing is next performed to assess the suitability for valve implant (B). This is followed by testing for coronary artery compression (C). During delivery of the Melody valve, the outer sheath of the Ensemble BDS is withdrawn and a small angiogram is performed to confirm the appropriate position for implant (D). Next the inner balloon (E) of the BIB catheter are expanded, fully deploying the Melody valve. A repeat PA angiogram demonstrates no residual stenosis or regurgitation (F). Fluoroscopy at the end of the procedure nicely demonstrates the Melody TPV inside the metal struts of the bioprosthetic valve in the AP, Lateral, and Down-The-Barrel view (G,H).

Figure 13.44. ICE evaluating Melody valve function. ICE has become a very important tool to evaluate the degenerating conduit valve as well as the newly implanted Melody TPV. The catheter is placed in the RVOT directly beneath the valve. Severely thickened and immobile valve leaflets are seen with systolic velocities over 3 m/sec and a wide diastolic color jet indicating significant PR (A). After the Melody TPV implant, nice thin leaflets are seen in systole and diastole with no significant residual stenosis or regurgitation (B).

The results of the expanded US Multicenter trial have recently been published by McElhinney et al. (68). Melody valve implantation was attempted in 124 patients, excluding, among others, 6 patients in whom valve implantation was not attempted due to coronary compression. Procedure-related serious adverse events occurred in 6% of patients including one death from intracranial hemorrhage after coronary artery dissection and one valve explantation after conduit rupture. Importantly, freedom from Melody valve dysfunction or reintervention was 94% at 1 year, and functional improvement in NYHA class was seen in most patients, even though long-term results after Melody valve implantation have yet to be confirmed. As an alternative to the Melody valve, the Carpentier-Edwards valve is presently undergoing trials within the US and may be suitable for larger RV-PA conduits (205,206).

HYBRID PROCEDURES

For many years, the relationship between the cardiothoracic surgeon and cardiac interventionalist was marked by competition and occasional “turf wars” between both groups, especially when dealing with acquired heart disease in adults. However, one of the most valuable lessons learned over the past decade is the need to embrace a collaborative approach between the congenital interventionalist and cardiac surgeon. Today, it should be commonplace to find a cardiac surgeon giving advice in the cardiac catheterization laboratory, while an interventionalist may aid his/her surgical colleague in the operating room by providing specific interventional techniques in selected patients. It should be routine and standard to involve the surgical team in any patient who is expected to undergo further surgical procedures prior to engaging in any transcatheter intervention. These discussions must be open and directed towards the specific patient who is being considered for interventional and/or surgical treatment. For example, in a patient undergoing transcatheter evaluation in preparation for conduit replacement, it may well be justified to place a stent for a more distal pulmonary artery stenosis, while proximal branch stenosis is not addressed because it is felt that this lesion could easily be treated during subsequent conduit replacement. Knowledge of the combined treatment capabilities allows the development of new and complex treatment strategies. One of the most notable examples of this cooperation has been in the “fenestrated Fontan” patients, in whom the immediate surgical morbidity is dramatically reduced by a purposeful “conduit” fenestration, which can subsequently be closed in the catheterization laboratory once the patient has recovered from the initial procedure. Another dramatic example of this type of collaboration is in patients with pulmonary valve atresia and VSD, in whom the surgical creation of a right ventricle to pulmonary artery connection early in the course of management provides the cardiologist access to the pulmonary vessels for dilation and intrapulmonary stenting in preparation for eventual definitive repair. This type of cooperation with inclusion of the adjunct procedures of the cardiologist in the staging of the surgery will contribute to better outcomes for many patients with extremely complex lesions.

In addition to the aforementioned collaboration between cardiac surgeons and cardiac interventionalists, a selection of new therapeutic hybrid catheterization and surgical procedures has been added to the spectrum of therapeutic interventions in complex CHD. These include the staged “hybrid approach” to the management of hypoplastic left heart syndrome (207–209), periventricular closure of VSDs (168,176), and intraoperative stent placements (210). Results of the multi-institutional C3PO registry documented a significant increase in the number of hybrid procedures performed over

a 2-year study period, with PDA stent placement, periventricular VSD closure, and intraoperative stent placement being the most commonly performed hybrid interventions (211).

Hypoplastic Left Heart Syndrome

Hypoplastic left heart syndrome carries a grave short- and long-term prognosis despite improvements that have been made in the traditional staged surgical approach. Even though surgical management has evolved over time, the basic concept has remained the same and as such, any possible improvements are capped by the limitations of this basic surgical approach. Using the conventional palliative surgical approach, the 5-year survival has been documented in multicenter experiences to be as low as 54% (212). The stage I Norwood- or Sano-type palliation in the neonate appears to carry the greatest risk contributing to the high morbidity and mortality in these patients. This is not surprising, given the many physiological changes that occur in the neonatal period that significantly influence the overall balance of this very fragile circulation. Combining this with an additional insult of a major open-heart procedure results in quite variable outcomes among institutions with mortality ranging from just under 10% to in excess of 50%. This has led to the development of alternative treatment strategies that are based upon smaller off-pump interventions in the early neonatal period that can be performed with minimal morbidity and mortality, thereby deferring the need for major cardiac surgical procedures, allowing the necessary time for improved growth and development of the patient and cardiac structures. This sets the stage for a subsequent comprehensive surgical procedure that combines the classical bidirectional Glenn shunt with a Norwood-type palliation as well as potential setup for subsequent transcatheter completion of the Fontan-type circulation. This staged approach requires a close collaboration between the cardiac surgeon, interventional cardiologist, and Heart Center staff. As is the case with many new innovative techniques, modifications have evolved over time as a result of the associated learning curve.

In 2002, Akintuerk et al. (213) reported on their experience with 11 patients who underwent transcatheter stenting of the arterial duct using balloon-expandable Jo stents, followed by bilateral pulmonary arterial banding 1 to 3 days after the transcatheter procedure. Balloon atrial septoplasty or BAS was performed on an as-needed basis. This early palliation was followed by a bidirectional Glenn procedure as well as a Damus-Kaye-Stanzel procedure and arch reconstruction between the age of 3.5 and 6 months. Two deaths were encountered in this series.

Figure 13.45. Hybrid Stage I for HLHS—Setup. Team approach during a Hybrid Stage I palliation in the specifically designed Hybrid Catheterization Suites.

Figure 13.46. Hybrid Catheterization Suite. Hybrid cardiac catheterization suite at Nationwide Children's Hospital.

In 2003, Michel-Behnke et al. (207) of the same group published an updated experience of 20 patients with very similar results.

The technique has further been modified by Galantowicz and Cheatham (208). Initial attempts at a sole transcatheter

technique with implantation of the AMPLATZER PA Flow Restrictor (AGA Medical, Golden Valley, MN) and PDA stents had a suboptimal outcome with significant hemodynamic compromise due to the combination of the stiffness of delivery cable as well as the need for placing a long sheath through tricuspid and pulmonary valves into the branch PAs, resulting in significant regurgitation. The approach was thus modified to a true hybrid technique, in which the cardiac surgeon initially performs bilateral pulmonary arterial banding, followed by transpulmonary placement of a stent to maintain patency of the arterial duct during the same procedure. This technique is performed preferably in a specially designed hybrid cardiac catheterization or operative suite that facilitates the specific needs of the cardiac surgeon as well as the interventional cardiologist (Fig. 13.45). The first suite dedicated to "hybrid" therapies in complex CHD opened in June 2004 at Nationwide Children's Hospital in Columbus (Fig. 13.46).

After LPA and right pulmonary artery (RPA) bands are placed using a 3.5- or 3.0-mm GoreTex tube that are cut into 1- to 2-mm-wide strips, the PDA stent is delivered through a short delivery sheath placed transpulmonary directly through a purse-string secured by snares. The initial choice of stents included balloon expandable premounted Genesis (Cordis, Warren, NJ) or Formula 418 stents (Cook, Bloomington, IN) but more recently self-expandable Protégé (EV3, Plymouth, MN) stents have been implanted and are felt to be more

Figure 13.47. Hybrid Stage I for HLHS—Procedure. A 2-day-old infant with hypoplastic left heart syndrome undergoing stage I palliation. **Top left and right:** MPA angiogram after placement of bilateral PA bands and a PDA stent. **Bottom left:** Placement of a stent across a restrictive intra-atrial communication. **Bottom right:** Angiogram after placement of a stent across the restrictive intra-atrial communication.

beneficial due to the increased flexibility when compared to the balloon expandable varieties. Additionally, the feasibility of allowing to “drag” the partially deployed stent backwards if required during the delivery process is useful. The use of these stents has become even more appropriate since the length of the delivery sheath has been decreased from 135 to 80 cm.

The hybrid stage I procedure is feasible for the majority of patients with hypoplastic left heart syndrome (Fig. 13.47), an exception being those patients with stenosis of the retrograde aortic arch with accelerated flow noted on screening Doppler echocardiography. In these patients, a classical Norwood-type procedure remains the preferred treatment choice. Size has not been an issue with hybrid stage I palliation being successfully performed in preterm neonates as small as 1.1 kg. After the hybrid stage I procedure, patients are usually evaluated prior to discharge for the presence of any significant atrial-level restriction and BAS or atrial septoplasty is performed in virtually all patients, unless a very large ASD is present. In patients with hypoplastic left heart syndrome, this procedure can be extremely challenging and may require a wide variety of techniques, such as RF perforation of the atrial septum, use of (cutting) balloon septoplasty, atrial septal stent placement, or BAS with a smaller 1-mL balloon catheters. Frequently, a combination of these techniques is used to achieve successful

relief of any atrial level restriction (72). Patients are closely monitored during the follow-up period not only for the development of recurrent atrial-level restriction but also for the presence of any obstruction at the level of the retrograde aortic arch or the PDA stent, as well as assessing the flow to both branch PAs. Ideally, a single catheterization procedure is performed prior to the comprehensive stage II procedure. This includes assessment of the distal pulmonary artery pressures using a pressure wire such as the Radi pressure wire (Radi Medical Systems, Uppsala, Sweden), and an assessment for any residual or recurrent stenosis across the PDA stent or retrograde arch (Fig. 13.48). A septostomy at this stage usually allows the use of a larger septostomy balloon and is performed if any significant atrial-level restriction is identified.

The comprehensive stage II procedure is mostly a surgical undertaking, often combined with completion angiography. It combines a bidirectional Glenn shunt with debanding of the pulmonary arteries and patch pulmonary artery augmentation, if required. A Damus-Kaye-Stanzel anastomosis is performed with arch reconstruction. The PDA stent is removed and atrial septectomy is performed. If a transcatheter Fontan completion is considered, radio-opaque bands can be placed across the IVC and a blind-ending pouch of SVC below the pulmonary arteries is created. Another radiopaque marker facilitates subsequent

Figure 13.48. Transcatheter evaluation after Hybrid Stage I palliation. A 5-month-old infant with a h/o Hybrid stage I palliation and ASD stent placement. Catheterization prior to comprehensive stage II includes pressure recording with pressure wires in RPA (A), LPA, retrograde arch (B), Dao through stent, and ASD. Angiograms in MPA and PDA stent show the RPA band (C), LPA band, PDA stent and retrograde arch (D).

transcatheter completion of a Fontan-type circulation. The transcatheter completion of the Fontan-type circulation requires the availability of a covered balloon expandable stent, which can be implanted between IVC and SVC-pouch. A catheter-based approach was first described by Hausdorf et al. (214) but it was only recently that this approach had been modified by Galantowicz and Cheatham (209). However, its practical use has been limited in the United States due to the lack of FDA approval of the covered stent. Outside the US, the covered varieties of the NuMED CP stent are more widely available and this has resulted in further development of this technique pursued by larger Canadian centers (215).

The hybrid approach has been documented to achieve acceptable short- and mid-term outcome in patients with hypoplastic left heart syndrome. Galantowicz et al. (216) reported a 97% hospital survival after Hybrid Stage I palliation, with a combined survival up to and including comprehensive stage II palliation of more than 80% in standard patients with HLHS. This compares very well to other purely surgical series. One of the main problems after Hybrid stage I palliation is the development of in-stent stenosis within the stented arterial duct, which not only leads to obstruction for the right ventricle but even more importantly can create or worsen obstruction of flow to the retrograde arch. Egan et al. (217) recently reported histological results taken from stented PDA segments

that documented that neointimal proliferation after PDA stent placement were the “result of inflammation, extracellular matrix deposition, and smooth muscle-cell proliferation in the peristut region.” Identifying those patients who are at risk of developing retrograde arch obstruction after PDA stent placement has been a particular challenge. Egan et al. (218) reported that patients with smaller aortic roots, higher baseline retrograde arch velocities, and a larger angle between retrograde arch and PDA on angiography may be at higher risk of developing retrograde arch obstruction.

This technique is still evolving and with refinements in patient selection, further improved morbidity and mortality should be realized. Special efforts are being made to evaluate the neurodevelopmental outcome in these patients, which ultimately may be the most important factor in comparing the surgical and the hybrid approach for palliation of HLHS.

Perventricular Closure of Ventricular Septal Defects

Device closure of muscular VSDs using the AMPLATZER Muscular VSD Occluder has been shown to be safe and effective. However, even though the transcatheter approach can be safely and effectively performed in most patients, patient weight below 10 kg has been associated with a significantly

Figure 13.49. Perventricular VSD closure. Closure of a moderate-sized muscular VSD in a 3-month-old infant using a perventricular “Hybrid” approach. **Top left:** Four-chamber view demonstrates large VSD. **Bottom left:** Four-chamber view with color flow mapping demonstrates VSD. **Top right:** Long-axis view documents excellent device position after VSD closure. **Bottom right:** Long-axis view with color flow mapping demonstrates only minimal foaming through the device after release.

higher risk of procedure- or device-related complications and a higher risk of procedural failure (170,219). This is mainly related to the need of establishing an arteriovenous wire loop and the use of a long and relatively stiff delivery system, which in infants, frequently not only stents open the tricuspid and aortic valves but also creates a significant amount of tension that may result in bradycardia and/or temporary heart block. As a result, a periventricular approach has been adopted that combines the safety of the hybrid surgical approach, avoidance of cardiopulmonary bypass, and relatively short procedure time. In this approach, the heart is exposed through a midline sternotomy off cardiopulmonary bypass. Under TEE and/or epicardial echo guidance, the appropriate entry site in relation to the VSD is identified and secured by placing a purse-string around its location at the RV free wall. Subsequently, a direct puncture is performed with the needle directed towards the VSD. A 0.035-inch angled glide wire is used to cross the VSD. An appropriately sized short hemostatic sheath can then be advanced across the VSD under echo guidance, keeping an appropriate distance from the LV free wall and the MV apparatus. The correctly sized AMPLATZER Muscular VSD Occluder is then loaded and advanced across the sheath and deployed under echo guidance, again, being specifically careful to establish some distance to the MV apparatus before deploying the LV disc. Once deployed across the VSD, device position is evaluated for any evidence of residual shunts or interference with adjacent structures that could create, for example, mitral or tricuspid regurgitation. Once a satisfactory device position has been confirmed, the device is released followed by a final echo evaluation (Fig. 13.49). The earliest experience describing this technique was reported by Bacha et al. (176) in 2003. In 2005, a multicenter experience documented successful application of this technique in 12/13 patients without mortality (168). At follow-up, residual shunts were present in two patients, without evidence of volume overload, congestive heart failure, or pulmonary hypertension. Modifications of this periventricular approach to facilitate closure of perimembranous VSDs have been evaluated in animal experiments by Amin (220).

Intraoperative Stent Placement and Other Hybrid Procedures

The cooperation between cardiac surgeon and interventional cardiologist is not limited to the management of infants with HLHS or periventricular VSD closure. The “hybrid approach” can and has been adopted to a variety of lesions and indications, including the stent placement in a variety of locations (Fig. 13.50) on and off cardiopulmonary bypass, vascular access in preterm Neonates requiring interventional therapy (such as carotid cutdown or direct puncture via sternotomy), and intraoperative balloon occlusion of aortopulmonary collaterals or shunts (Fig. 13.51). The ability of the surgeon to provide safe access to a vascular structure not amenable to conventional transcatheter therapy and the ability of the interventionalist to use less-invasive techniques and materials creates a unique “marriage” benefiting patients with complex CHD. The essential ingredients to achieve a successful outcome of these procedures are the close cooperation between the surgeon and interventionalist as well as their flexibility to adopt nonstandard approaches that are specifically tailored towards each individual patient.

Intraoperative stent placement is aided by the direct visualization in the operative field and can be further enhanced through the use of endoscopic equipment that facilitates a more detailed view of the stenosed or compressed area. The decision about intraoperative stent placement often is made in the catheterization laboratory, especially when evaluating

Figure 13.50. Intraoperative PA stenting. A 7-year-old girl with complex CHD who underwent intraoperative LPA stent placement during a Mustard procedure. **Top:** PA angiogram demonstrates a severely hypoplastic LPA. **Middle:** Intraoperative PA rehabilitation monitored endoscopically, from left to right and top to bottom, cutting balloon angioplasty, (covered) stent positioning followed by expansion, stent appearance after expansion. **Bottom:** PA angiogram demonstrates significantly improved LPA appearance.

Figure 13.51. Stent placement via carotid cutdown. A 2-month-old boy premature infant (2.1 kg), who initially underwent Hybrid stage 1 palliation for complex CHD developed a significant recoarctation distal to the left subclavian artery (LSA) and therefore underwent “Hybrid” placement of a premounted stent using a surgical carotid cutdown. **Left:** Almost complete interruption distal to LSA before stent placement. **Right:** Aortogram after stent placement demonstrates significantly improved flow through the DAO.

Figure 13.52. Intraoperative stent placement in proximal PA in adult using endoscopic guidance. A 42-year-old patient with history of Tetralogy of Fallot repair and free pulmonary insufficiency. Presurgical catheterization documented an LPA kink (A,B). Intraoperative endoscopic evaluation documented a ridge/fold at the proximal LPA (C), which was successfully treated by intraoperative stent placement (D).

Figure 13.53. Hybrid operating suite. “Hybrid” operating suite at Nationwide Children’s Hospital in Columbus, Ohio, with large amount of floor space and various adjustable monitors combined with strategically placed booms. Equipment includes among others a ceiling-mounted cardiac flat-panel detector (Toshiba America Medical systems, Tustin, CA).

adult patients who are expected to undergo surgical conduit or pulmonary valve replacement. While proximal branch PA stenoses may be easily addressed during the surgical intervention, a more distal stenosis should usually be treated in the cardiac catheterization laboratory. Any residual branch PA stenosis after surgical pulmonary valve replacement burdens extra strain on the already reduced RV function, and therefore appropriate rehabilitation of these lesions is extremely important in achieving a quick postoperative recovery of RV function. However, a very proximal branch PA stenosis may not necessarily always indicate the need for surgical angioplasty. In fact, a nonobstructed RVOT may not always be treated with placement of a pulmonary valve, rather than placing an RV-PA conduit and as such a proximal branch PA stenosis may be better treated by placing an endovascular stent rather than performing patch

angioplasty with its fairly high recurrence risk (Fig. 13.52). In many instances, the ultimate decision whether to stent or to surgically treat the stenosis will be made intraoperatively. Intraoperative stent placement is a valid treatment option for these patients, with recent studies having documented very good results (221).

In addition, it is essential to have a high-resolution, digital, mobile C-arm readily available to obtain intraoperative angiograms whenever necessary. Hybrid Cardiothoracic Operative Suites with integrated permanent imaging equipment (Fig. 13.53) allow even more complex CHD to be treated using innovative management strategies. However, appropriate radiation protection is essential during these procedures, especially to surgeon and other operating room staff who are not accustomed to working with fluoroscopic equipment. While the need for radiation protection for staff and patients in the catheterization laboratory is frequently emphasized (222), the radiation protection used is usually impractical for surgeons in the operating room. As a result, Sawdy et al. (223) recently reported the use of lightweight radiation protection drapes that can be used during these hybrid procedures.

Holzer et al. (224) recently published the results of completion angiography performed after 32 cardiac surgical procedures, identifying unexpected pathology in 56% of procedures, leading to therapeutic changes or interventions in 28% of patients (Fig. 13.54). Other examples of important pathology identified through intraoperative C-arm angiography have been reported by Shuhaiber et al. (225). These reports emphasize that completion angiography after cardiac surgical repair may be an underutilized diagnostic modality, with potentially as important an impact on outcome as has been established with routine intraoperative TEE.

SUMMARY

The therapeutic cardiac catheterization procedures discussed in this chapter represent significant advances in the care of patients with CHD. The procedures are ordinarily performed

Figure 13.54. Exit angio after comprehensive stage II with inraop LPA stent. A 6-month-old boy infant with HLHS and previous Hybrid Stage I palliation. Exit angiography after comprehensive Stage II palliation documented a significant stenosis (patch-folding) of the mid-portion of the LPA (A). A 25-mm Genesis XD stent was implanted and expanded to 7 mm with very good angiographic result (B).

without an incision, cardiopulmonary bypass, or chest tubes. Some of the therapeutic procedures are possible only in the catheterization laboratory, and the subsequent surgery is possible only after preparation in the catheterization laboratory.

Even with the additional expense of the specialized catheters and devices and the added cost of the more extensive catheterization procedures, the direct costs of the therapeutic procedure in the catheterization laboratory are significantly lower than those for the comparable surgical procedure. The indirect savings for a patient or the patient's family may be even greater. The patient and family are away from home and work for only 1 or 2 days for the entire hospital stay. Following the catheterization procedure, the patient can return home and immediately return to full activity of either school or work. These advantages of therapeutic catheterization procedures have led to their wide acceptance.

However, therapeutic catheterization has advanced beyond the confines of the cardiac catheterization laboratory. Many "cutting-edge" procedures can only be facilitated through the unique cooperation between cardiac surgeon and interventional cardiologist and as such, patient care is advanced through this combined expertise. With further developments and improvements in catheter and surgical techniques, it is to be expected that additional nonsurgical or "hybrid" corrections will become standard within the next several years (226–229).

Development and Functional Maturation of the Cardiac Conduction System

Aleksander Sizarov ■ Antoon F.M. Moorman ■ Arthur S. Pickoff

In this chapter, current concepts regarding the formation of the cardiac conduction system, along with developmental aspects of cardiac electrophysiology, are summarized. Genetic regulation of the early specification of the conduction system and the electrophysiologic characteristics of the maturing heart are discussed in conjunction with morphologic considerations.

RECOGNITION OF THE CONDUCTION TISSUES IN THE POSTNATAL HEART

All cardiac muscle possesses the capacity to conduct, making the term “conduction system” a bit ambiguous. A small subset of cardiomyocytes, nonetheless, has specific electrophysiologic properties, accompanied by a distinct cellular morphology and pattern of gene expression. These cardiomyocytes make up the so-called specialized conduction system of the heart. The conduction system consists of the sinus node, the atrioventricular (AV) node, the AV bundle (known better in the clinical setting as the bundle of His), its branches, and the ventricular network of Purkinje fibers (Fig. 14.1A). Each time the heart beats, contraction is triggered by a wave of electrical activity spontaneously generated in the sinus node. The depolarizing impulse propagates rapidly through the atrial chamber myocardium, to be collected and delayed in the AV node, and again spreads very rapidly to the ventricular muscular mass through the bundle of His, its branches, and the ramifications of the Purkinje fibers. Comprehensive histologic descriptions of the cardiac nodes and the fast-conducting tracts were published over a century ago (1–4) and have served as the “gold standard” for the identification of the specialized conduction tissues.

The characteristic aggregation of the cardiomyocytes at specific locations, either as nodes or as tracts, makes it possible to recognize them as anatomic components of the conduction system by routine histology (Fig. 14.1B). In the human heart, the sinus node (SN) occupies a subepicardial position at the lateral aspect of the junction of the superior caval vein (SCV) and right

atrium (RA) (5). The node characteristically is horseshoe shaped in the fetus, and usually assumes a more spindle-like shape with development. By light microscopy, the cells of the SN morphologically are distinct from the surrounding atrial myocardium; they are smaller, more compact, and contained within a fibrous matrix (6). A tail of nodal cells extends inferiorly from the SN along the terminal crest of the atrium. The AV node is located within the right atrial wall at the apex of the triangle of Koch, which is bordered by the septal leaflet of the tricuspid valve, the tendon of Todaro, and the mouth of the coronary sinus (7). Histologically, the AV node consists of a zone of loosely arranged “transitional” atrial cells that blend and extend into the surrounding atrial myocardium and, adjacent to the central fibrous body, a compact zone of closely grouped small cells (8). Two inferior extensions from the compact zone have been described that extend toward the hinges of the mitral and tricuspid valves (9,10). The compact zone of the AV node continues to penetrate the central fibrous body, at which point it contacts the bundle of His. Subsequent to penetrating the central fibrous body, and at the crest of the muscular portion of the ventricular septum and beneath the membranous septum, the bundle of His becomes the branching bundle, which gives rise to the right and left bundle branches (1,8,11). These then course along the surface of the ventricular septum toward the apex of the heart as muscular tracts insulated from the rest of the ventricular myocardium by fibrous tissue. The left bundle branch divides further into three fascicles. Under light microscopical inspection, the cells of the bundle branches appear slightly larger than the surrounding myocardial cells. The terminations of the bundle branches continue as a widespread network of Purkinje fibers, which in the human heart are little different from the adjacent working cardiomyocytes. They are subendocardially localized, and branch into small transmural ramifications (12). The so-called AV ring bundles (13), and septal and retroaortic (RAo) root branches (14,15), generally are not considered as components of the definitive AV conduction system in the normal adult heart. They still can be traced, however, in neonatal human hearts (Fig. 14.2), and can persist as histologically recognizable structures. In rare circumstances, these remnants may provide the substrate for

Figure 14.1. Anatomy and histology of the cardiac conduction system in the postnatal heart. **Panel A** shows schematic representation of the location of the conduction system components in relation to the external and internal cardiac anatomy (Modified from Heart and Great Vessels. In: Standring S (Ed.). *Gray's Anatomy: The Anatomical Basis of Clinical Practice*. 40th ed. Churchill Livingstone, 2008; pp 959–987.) The lateral wall of the RA and RV was removed to expose the conduction tissues (depicted in blue). **Panel B** shows histological sections through the sinus node, AV node and penetrating portion of the bundle of His in the heart of a 7-month-old child. Sections were stained using Masson's trichrome technique, which stains muscle tissue in red and collagen fibers in blue. Note the differential staining within the cardiac nodes and the bundle of His, the latter being additionally surrounded by connective tissue. The AV node comprises the compact part and more loosely arranged fibers of the so-called transitional atrial cells. AV, atrioventricular; CFB, central fibrous body; SN, sinus node; TV, tricuspid valve.

some forms of ventricular preexcitation in otherwise normally structured hearts (16). Additionally, in the setting of complex congenital malformations, these remnants may constitute the AV conduction axis at aberrant locations (see below).

The sporadic appearance of individual cardiomyocytes resembling so-called Purkinje cells in the atrial musculature between the cardiac nodes, and in the pulmonary venous sleeves, caused some authors to conclude that these cells constitute specialized conduction tissue at these ectopic locations (17,18). In the postnatal heart, however, the preferential con-

duction that exists within the atrial musculature is explained by the orientation of the cardiomyocytes, rather than the existence of specialized tracts (19). As discussed later, the maintenance of the primary myocardium phenotype, or insufficient maturation of the working myocardium of the terminal crest, the sleeves around the pulmonary veins, and the ventricular outflow tracts (OFTs) during cardiac development could provide the substrates for abnormal automaticity in the postnatal heart. In terms of gross histology, however, these areas are indistinguishable from the remainder of the working myocardium (20–22).

Figure 14.2. Definitive and “residual” components of the AV conduction system. The derivatives of the “primary ring” (depicted in red) from which the AV conduction system is derived are projected on the superior view of the aortic-mitral fibrous unit (orange) of the postnatal heart. Blue dots indicate the areas of remnants of the “residual” derivatives of the “primary ring,” which can be found in neonatal human hearts. AV, atrioventricular; RAo, retroaortic. (Modified from Wesels A, Mijnders TA, de Gier-de Vries C, et al. Expression of myosin heavy chain in neonatal human hearts. *Cardiol Young* 1992;2:318–334.)

THE BASIC BUILDING PLAN OF THE MAMMALIAN HEART

A fundamental question in cardiac development relates to the establishment of the correct disposition of the chambers and the conduction system. In the early developing heart, it is not possible to identify, histologically, components of the conduction system as one can in the postnatal heart. Subsequent to formation of its chambers, nonetheless, the embryonic heart produces coordinated contractions and relaxations of the atria and ventricles, which is reflected in the nearly “adult-like” electrocardiogram (23) (Fig. 14.3). The developing heart consists of several building blocks with distinct conduction and contraction properties, which allow for efficient pumping function of the heart despite the absence of a definitive conduction system and valves (24).

Early cardiac development starts around 20 days of human embryonic life (see Table 14.1). The first step is the formation of a primary heart tube from the cardiogenic mesoderm, the latter known as the cardiac crescent. The primary heart tube in vertebrate embryos is little more than a myocardialized part of the splanchnic mesodermal layer folded and protruding into the coelomic cavity. It encompasses a narrow lumen lined by a single layer of endothelial cells, with a thick acellular layer of cardiac jelly separating the endothelium from the outer myocardial layer (25,26). This simple myocardial tube produces unidirectional peristaltic waves of contractions, which propel the blood from the inflow to the outflow part of the heart tube. Not all mesodermal cells fated to become cardiomyocytes do so immediately. At the venous and arterial poles, along with the dorsal mesocardium, which are the sites of attachment of the primary heart tube to the dorsal part of the embryo, differentiating cells from the pool of cardiac progenitors, the so-called second heart field, are added to the heart (27–29). This permits the slowly proliferating primary heart tube to significantly elongate during a relatively short period of time (30,31). Concomitantly, the primary heart

Figure 14.3. Configuration and electrocardiogram of the early chamber-forming heart in the chicken embryo. **Panel A** shows a scanning electron microscopic image of a stage 17 chicken looping heart, where ballooning of the atrial and ventricular chambers has just been initiated at the outer curvature of the heart tube. Arrows point to the angles at the caudal and cranial borders of the proximal outflow (PO) tract. (From Männer J. The anatomy of cardiac looping. *Clin Anat* 2009;22:21–35, with permission.) **Panel B** shows an electrocardiogram derived from a chicken embryonic heart at a comparable stage of development. Note the almost “adult-like” ECG, including the isoelectric interval between the P wave and QRS complex. AV, atrioventricular canal; LA/RA, left/right atrium; LV/RV, left/right ventricle. (From Paff GH, Boucek RJ, Harrell TC. Observations on the development of the electrocardiogram. *Anat Rec* 1968;160:575–582, with permission.)

tube loops ventrally and rightward, so that it becomes possible to recognize its outer and inner curvatures (Fig. 14.4). At localized areas of the outer curvature, the primary cardiomyocytes start to proliferate, at the same time initiating a genetic program governing their differentiation toward the working myocardium phenotype characterized by expression of fast-conducting gap-junctional proteins and atrial natriuretic factor (ANF) (31–33) (Fig. 14.5). The myocardium of the ballooning atrial and ventricular chambers remains flanked by the primary myocardium of the AV canal, the inner curvature, and the OFT. These flanking segments retain the primitive phenotype characterized by long-lasting contractions and slow conduction (24). After initiation of chamber formation, a new myocardial structure, the systemic venous sinus, or sinus venosus, is formed at the inflow region of the heart (34). Similar to the myocardium of the primary heart tube, the myocardium of the venous sinus initially escapes further differentiation, does not express fast-conducting connexins, and is characterized by high intrinsic automaticity, ensuring dominant pacemaker activity at the inflow of the heart (35–38). At this stage, the basic cardiac building plan, consisting of fast-conducting chambers flanked by slow-conducting myocardium of the

Figure 14.4. Morphogenesis of the early heart tube in mammals. **Panel A** depicts the prototypic linear heart tube as seen in ventral (left) and right lateral (right) views, while **panel B** shows the prototypic looping and chamber-forming heart tube in similar views. The primary myocardium is indicated in gray, the secondary myocardium of the atrial chambers ballooning at the dorsal aspect of the heart tube (arrows) is indicated in blue, and the myocardium of the ventricular chambers growing ventrally along the outer curvature of the heart tube (arrows) is indicated in red. At the linear tube stage no secondary myocardium is present. In the human embryonic heart, the chamber myocardium is first seen locally at the stage of looping and does not involve the entire circumference of the tube. Note that the primary myocardium of the venous pole, the atrioventricular canal (AVC), and the outflow tract (OFT) is contiguous, with no signs of separate rings of so-called specialized tissue. AVC, atrioventricular canal; LV/RV, left/right ventricle; OFT, outflow tract. (Modified from Moorman AFM, Christoffels VM. Cardiac chamber formation: development, genes, and evolution. *Physiol Rev* 2003;83:1223–1267.)

Figure 14.5. Three-dimensional and molecular analysis of chamber formation in the human embryonic heart. Two different stages are shown. Panels A,A*,A** show a 3-D model and immunohistochemical stainings for chamber markers in the stage 12 embryonic heart, when the chamber formation is initiated. Note, that the walls of the atrioventricular canal (AVC) and inner curvature (*dotted line* in A**) do not express atrial natriuretic factor (ANF) and connexin40, while the walls of the atrial and ventricular chambers are positive for these markers. Panels B,B*,B** show a 3-D model and stainings in the stage 14 heart, when septation between the atrial and ventricular chambers is initiated. Now clearly two separate atria are formed and the ventricular chambers possess an extensive meshwork of trabeculations. Note, that the walls of the venous sinus (SV) and AVC (*arrowheads*) are still negative for chamber markers. AVC, atrioventricular canal; LA/RA, left/right atrium; LV/RV, left/right ventricle; OFT, outflow tract; SV, sinus venosus. (Modified from Sizarov A, Ya J, de Boer BA, et al. Formation of the building plan of the human heart: morphogenesis, growth, and differentiation. *Circulation* 2011;123:1125–1135.)

venous sinus, atrioventricular canal (AVC), and OFT serves as a blueprint for the formation, at appropriate positions, of the specialized pacemaking and conduction system (39).

THE SINUS NODE

Initiation of the Heart Beat

Subsequent to its formation, the primitive heart tube immediately commences regular waves of peristaltic contractions. At the beginning, the initiation of contraction is observed in the middle of the straight heart tube (40), where excitation–contraction coupling of the cardiomyocytes has progressed sufficiently to produce active shortening of the myofibrils. Studies in chicken embryos using voltage-sensitive dyes detecting spontaneous electrical depolarization have demonstrated that pacemaker activity can be identified along the whole primary heart tube prior to any contractile activity (41)

(Fig. 14.6A). However, the earliest spontaneous pacemaking activity always is located at the inflow of the primary heart tube (38) (Fig. 14.6B). During further development, the pacemaking activity in already differentiated myocardium is suppressed, while newly added myocardium at the venous pole assures this site remains the dominant pacemaker site (38,42), ensuring efficient unidirectional pumping of the blood. The pacemaking mechanism in the adult SN is very complex, and involves multiple currents through different ion channels (43). It is still incompletely characterized in the embryonic heart. Very early in embryonic life, prior to the development of true pacemaker ion current(s), shuttling of calcium in and out of the sarcoplasmic reticulum through an inositol triphosphate-dependent mechanism may be responsible for pacemaker activity (44). Mouse embryos that are deficient for the hyperpolarization-activated cyclic nucleotide-gated cation channel 4 (HCN4), the major isoform producing the I_f (“funny” current), have extremely low heart rates and die in utero (45), suggesting an important role of I_f in the pacemaking mechanism of the embryonic heart.

Figure 14.6. Initiation of the heart beat. **Panel A** shows that in the very early chicken embryonic heart (about stage 9), which is not yet contracting, action potentials of spontaneous depolarization can be detected over the entire heart tube. **Panel B** shows that the earliest action potentials always are registered at the most caudal end of the heart. Note, that the interval between the upstroke of the action potentials measured at proximal (1) and distal (2) sites of the heart tube remains remarkably similar at stage 13 as compared to very young stage 9 (*red bars* in **panel B**). The initial phase of the caudal action potential, however, already resembles at stage 13 the slow depolarization period of the definitive pacemaker action potential (*arrow* in **panel B**). AVC, atrioventricular canal; E, site of ECG registration. (Modified from Kamino K, Komuro H, Sakai T, et al. Functional pacemaking area in the early embryonic chick heart assessed by simultaneous multiple-site optical recording of spontaneous action potentials. *J Gen Physiol* 1988;91:573–591; and Van Mierop LHS. Localization of pacemaker in chick embryo heart at the time of initiation of heartbeat. *Am J Physiol* 1967;212:407–415.)

Development of the Sinus Node

The primary heart tube, although consisting of cardiomyocytes, which all possess pacemaker activity (40,46), does not contain the precursors of the cells destined to form the definitive sinus node, as at this stage the cardiomyocytes forming the systemic venous sinus have not yet been added to the heart (34). Early investigations of the developing cardiac conduction tissues in mammalian and human embryos were, of necessity, limited to search for clusters of histologically “specialized” cardiomyocytes at the locations they occupy in the postnatal heart. There are numerous comprehensive descriptions of the morphologic changes during development of the SN in the human embryonic and fetal heart (47–51). Although these studies were based on comparable histologic stainings, they led to very different hypotheses about its development. Thus, in the human, the SN had been hypothesized to develop from a so-called sinatrial ring (49,50). This concept depended on the presence of “specialized” rings of myocardium between segments of the pri-

mary heart tube, which, in turn, were believed to develop into the distinct parts of the definitive conduction system. Numerous molecular studies in experimental animals, and now in human hearts, have revealed that this is not the case.

From analyses of various transgenic mouse models, it is known that correct expression of several transcription factors is needed for the formation of the SN at its normal location (52) (Fig. 14.7). Until embryonic day 9 to 9.5 in mouse, and approximately 26 to 28 days in humans, the homeobox transcription factor *Nkx2.5* is expressed in all myocardium, but not in the mesenchymal cells at the caudal ventral side of the inflow tract (34,36). These cells express the T-box transcription factor *Tbx18* in a strictly complementary pattern, and differentiate into cardiomyocytes forming sinus muscle, and ultimately the sinus node. Genetic lineage analyses have provided strong evidence for the origin of the entire venous sinus from these cardiac progenitor cells. Taking into account that these cells are the precursors of the sinus node, this finding is consistent with the previous observation that the elongating heart tube shows

Figure 14.7. Molecular pathways regulating sinus node (SN) development. The SN develops from the sinus myocardium, which in turn differentiates from the Tbx18-positive and Nkx2-5-negative mesenchyme at the inflow region of the early chamber-forming heart. Depicted transcription factors regulate the formation of the boundaries and zones of expression and differentiation of atrium, SN and the myocardial sleeve of superior caval vein (SCV). Green arrows indicate positive regulation and red lines suppression of the sinus muscle and atrial muscle differentiation. For more details, see text. CS, Carnegie stage; E, embryonic day; pos, positive; SCV, superior caval vein; SN, sinus node. (Modified from Christoffels VM, Smits GJ, Kispert A, et al. Development of the pacemaker tissues of the heart. *Circ Res* 2010;106:240–254.)

an increase in beat rate (53). Furthermore, Tbx18-deficient mice fail to form the large head component of the sinus node, demonstrating that Tbx18 is crucial for the recruitment of inflow region mesenchyme into the myocardial lineage, which is essential for the formation of the SN (54). In the human embryonic heart, the systemic venous sinus is first discernable at 28th day of human development as a small hollow structure upstream from the common atrial chamber. It initially has nonmyocardial walls expressing Tbx18 and HCN4, and is no more than the confluence of the systemic venous channels entering the heart. During the next stages, the venous sinus shifts to the right, and its walls become muscular and thickened, particularly its right lateral part (36,55,56) (Figs. 14.8 and 14.9). This thickened structure, which may be considered as the sinus nodal primordium, is traceable at its specific location along the right side of the sinuatrial junction till the end of the embryonic period, when it already begins to resemble the SN of the postnatal heart (50). Early specification of the sinus nodal primordium in the mouse embryonic heart is regulated by another T-box transcription factor Tbx3 (57), which is expressed in the human embryonic heart in an almost identical pattern. Tbx3 represses the expression of the fast-conducting connexins 40 and 43, thus allowing newly added sinus myocardium to escape from further differentiation toward working myocardium (Fig. 14.9). Forced expression of Tbx3 in the atrial myocardium of the postnatal mouse heart leads to the development of ectopic functional pacemaker tissue, thus identifying Tbx3 as a key regulator of the sinus nodal phenotype (57). The suppression of the formation of the SN at the left side of the sinuatrial junction in the mouse heart is regulated by the transcription factor Pitx2c (42), which, in vertebrates, plays a crucial role in the establishment of the left/right asymmetry of the inner organs, including the heart (58). Accordingly, dual

sinus nodes are present in Pitx2c-deficient mice and in humans with right isomerism of atrial appendages (59).

During the mid-stages of human and mouse gestation, the expression of HCN4 and pacemaker activity becomes confined to the SN itself by an as yet undiscovered mechanism. The myocardium derived from the sinus muscle, with the exception of the SN itself, matures to produce a phenotype comparable to that of the atrial working myocardium, including upregulated expression of connexins 40 and 43, and downregulated expression of HCN4 (42). The failure of complete “atrialization” of this myocardium in some individuals could explain the presence of ectopic automaticity, and the initiation of ectopic atrial tachycardias.

THE AV CONDUCTION AXIS

The Development of the AV Conduction System

The myocardium of the primary heart tube is characterized by slow transmission of the electrical impulse. With ongoing development, the primary myocardium at specific locations along the outer curvature of the looping heart tube begins to further differentiate and expand to form the atrial and ventricular chambers, which are characterized by fast conduction of the depolarizing electrical impulse, and matching synchronous contractions (32,60). The ballooning chambers remain flanked by the primary myocardium of the venous sinus, inner curvature, AVC and OFT, which escapes further differentiation, and retains the more primitive phenotype displaying high automaticity, slow conduction, and long-lasting contractions (24). The different components of the definitive AV conduction system are formed

Figure 14.8. Three-dimensional and molecular analysis of the venous pole of the embryonic human heart. Panels A through C show different views of the 3-D model of a stage 14 human embryonic heart, on which the expression domain of fast-conducting gap-junctional protein connexin40 was projected (depicted in pink). Note that the myocardial wall of the venous sinus (asterisk) is negative for connexin40. Lines in (A) and (B) refer to the level of the transverse cut shown in panel C and histological sections shown in panels D and E. Serial sections through the venous sinus were stained for the transcription factor NKX2-5, which is not expressed in the walls of systemic venous tributaries (venous sinus, coronary sinus), and TBX18, which is expressed specifically in the walls of the venous sinus and coronary sinus and not in the rest of the cardiac muscle. Asterisk points to the vestibular spine. AVC, atrioventricular canal; cor, coronary; LA/RA, left/right atrium; LV/RV, left/right ventricle; OFT, outflow tract; pulm, pulmonary; SV, sinus venosus. (Modified from Sizarov A, Anderson RH, Christoffels VM, et al. Three-dimensional and molecular analysis of the venous pole of the developing human heart. *Circulation* 2010;122:798–807.)

in situ from this primary myocardium (61). The hypothesis that the conduction system may have contributions from the cardiac neural crest cells (62–64) has not been supported by overt evidence. In chicken embryos, retrovirus-labeled neural crest cells were not traced in the conduction system components (65), demonstrating that the entire conduction system has a myogenic origin. The cells derived from the neural crest differentiate in part into the autonomic nerves, which, in turn, influence the conduction properties through the AV conduction axis (66).

Although in the embryonic heart it is not possible to recognize the components of the AV conduction axis as seen in the postnatal heart, and the common atrium is in muscular continuity with the developing ventricles through the AVC musculature (67), the chamber-forming heart already displays coordinated atrial and ventricular contractions and a proper AV delay. As with the sinus node, standard histology does not permit the unambiguous identification of different tissue types. Nonetheless, investigators at the beginning of the previous century attempted to identify the precursors of the AV conduction

system in the human embryonic heart (47–49,68–73), but their conclusions were far from comparable. The AV node was claimed to represent a part of the original AVC, and it was suggested that the bundle of His arose from the nodal tissue by a process of active growth (47). Others hypothesized that the development of the AV node occurred through further specialization of the earlier appearing bundle of His (48). Still others postulated that the formation of the AV conduction system occurred through fusion of different parts of the “specialized” myocardial rings (49). More accurate insights into the development of the AV conduction system were gained from studies on the changes in expression of neural tissue antigen GIN2 during human cardiac development (74,75). Initially, in the early chamber-forming heart, GIN2 expression marks the so-called primary foramen, which is bordered by the right-sided aspect of the AVC and the crest of the ventricular septum. With ongoing development, the AVC expands and shifts rightward, establishing a direct connection between the RA and the right ventricle (RV), marked by the expression of GIN2.

Figure 14.9. Gene expression in the SN primordium. **Panel A** shows serial sections taken through the SN primordium (arrow) of a stage 16 human embryonic heart and stained immunohistochemically for the transcription factor TBX3 (left), gap-junctional protein connexin40 (Cx40, middle) and pacemaker ion-channel HCN4 (right). Note that TBX3 only is expressed in a part of the thickened wall of the venous sinus, which at this stage of development is in its entirety positive for HCN4 and negative for connexin40. **Panel B** shows the sinoatrial boundary in the mouse. In the hearts of wild-type mouse the expression of *Tbx3* and connexin40 are strictly complementary, while in the mouse heart, in which *Tbx3* was knocked-out, expression of connexin40 is extended into the sinus node. ra, right atrium; san, sinoatrial node. (From Hoogaars WMH, Engel A, Brons JF, et al. *Tbx3* controls the sinoatrial node gene program and imposes pacemaker function on the atria. *Genes Dev* 2007;21:1098–1112, with permission.)

A leftward extension of the anterior aspect of the GIN2-positive ring becomes evident at later stages, when the subaortic OFT becomes positioned above the left ventricle. In addition to the GIN2 expression on the crest of ventricular septum, at late stages, GIN2 positivity is also present along the surface of the ventricular septum, resembling the branches of the bundle of His (74) (Fig. 14.10). Although the functional significance of the expression of the neural tissue antigen GIN2 in the developing heart is still unknown, this marker has helped in the understanding of the development of the correct AV and ventriculo-arterial arrangements (76,77), and demonstrated that the entirety of the AV conduction axis developed from the primary ring myocardium.

Our insight into the molecular mechanisms regulating the further development of the AVC has increased over the last decade (Fig. 14.11). One of the earliest events is the activation of the bone morphogenetic protein (Bmp) signaling pathway, with *Bmp2* as one of the main players (78,79). This small signaling molecule activates the expression of another T-box transcriptional factor, *Tbx2*, which along with the transcription factors *Tbx3* and *Msx2* prevents expression of the chamber myocardium-specific genes, thus protecting the AVC muscle from further differentiation (80–83). Another T-box transcription factor, *Tbx20*, directly interferes with Bmp/Smad signaling to suppress *Tbx2* expression in the chambers, thereby confining *Tbx2* expression to the prospective AVC region (84). The combined action of the widely expressed transcription factors

Nkx2-5, *Tbx5*, and *Id2* (inhibitor of DNA binding), having more limited domain of expression, is now known to be crucial for the development of the AV conduction system in the mouse heart (85). In addition, recent lineage analyses in the mouse has provided evidence that structures, such as the coronary sinus, epicardium, vestibular spine, and ventricular septal myocardium, do not contribute to the formation of the AV node (86), as had been suggested previously (87,88) (Fig. 14.12). Current studies support the view that the embryonic AVC, although proliferating very slowly, grows sufficiently to provide the precursor cells for the AV node, AV ring bundles, and lower atrial rims. The same lineage studies also showed that the so-called lower nodal cells of the mouse heart and the ventricular parts of the AV conduction system, including the bundle of His, bundle branches, and the septal branch are not derived from the AVC, but have a ventricular origin (86). A cross-comparison of the genome-wide expression profiles of the cardiomyocytes from the AVC at E10.5 and the AV node at E17.5 in mouse revealed that the majority of differentially expressed transcripts at the E10.5 AVC had maintained this expression profile at the E17.5 AV node. Moreover, the AV nodal cells showed an extensive neurogenic gene expression profile, which is significantly different from that of the AVC, demonstrating that the AV node substantially specializes during development (89).

The myocytes making up the bundle of His and its branches are distinct from the myocytes of the AV node in terms of gene expression, as well as in their electrophysiological properties.

Figure 14.10. Development of the AV junction in the human embryonic heart based on the expression of neural tissue antigen GIN2. In the stage 13 to 14 heart (panels A,A*) a single ring of GIN2-staining tissue is identified, which marks the myocardium of the crest of the ventricular septum and right-sided part of AV canal surrounding the primary foramen connecting the cavities of the left and right ventricular chambers. In the stage 15 to 16 heart (panels B,B*) the GIN2 staining marks the rightward expansion of the AV canal, which establishes a direct connection between the RA and RV. In the stage 18 to 23 heart (panels C,C*) the leftward extension of the ventral part of GIN2-positive ring occurs as the subaortic OFT becomes positioned over the left ventricle. These drawings illustrate the development of the AV conduction system as a derivative of the GIN2-positive myocardium encircling the “primary” foramen in the earliest stages. The drawings show that the so-called septal branch and retroaortic (RAo) root branch can be recognized as transient structures in the developing human heart, which lose their GIN2 expression during late stages of development. AV, atrioventricular; cor, coronary; LA/RA, left/right atrium; LC/RV, left/right ventricle; VS, ventricular septum. (Modified from Wessels A, Vermeulen JL, Verbeek FJ, et al. An immunohistochemical analysis of the distribution of the neural tissue antigen GIN2 in the embryonic human heart. *Anat Rec* 1992;232:97–111.)

A variety of origins of the bundle of His have been proposed (90), but it is generally agreed that the bundle forms in situ by differentiation of the cardiomyocytes on the crest of the developing ventricular septum (61). Once more, *Tbx3* plays an important role in this process (91). From the outset, the crest of the ventricular septum is in direct continuity with the myocardium of the AVC dorsally and ventrally (92). Despite their distinct developmental origins, both the atrial and ventricular parts of the developing AV conduction axis express similar sets of molecular markers, including *Tbx3* and *HCN4*, and both initially are negative for fast-conducting connexins 40 and 43 (61) (Fig. 14.13). Although specified precursors of the bundle of His and its branches are present from the outset

of ventricular septation, they are not initially functionally able to rapidly propagate the electrical impulse (93).

Formation of the AV Plane of Fibrous Insulation

In the normal human adult heart, there are no other muscular connections between the atria and ventricles than the AV conduction axis, which is responsible for the delay of impulse propagation from the atria to the ventricles, this occurring in the AV node, and the uniform and rapid distribution of the impulse to the ventricular chambers through the bundle of His and its branches. As we already have emphasized, in the

Figure 14.11. Molecular pathways regulating the development and boundary establishment of the AV canal and chamber myocardium. *Green arrows* indicate positive regulation and *red lines* suppression for differentiation towards the working phenotype or retention of the more primitive phenotype. Note that broadly expressed transcription factors Tbx5, GATA5, and NKX2-5 play role in both processes, pointing to the importance of the cooperative action of several factors in regulating the fate of the cardiomyocyte. ANF, atrial natriuretic factor; AVC, atrioventricular canal; CS, Carnegie stage; E, embryonic day. (Modified from Christoffels VM, Smits GJ, Kispert A, et al. Development of the pacemaker tissues of the heart. *Circ Res* 2010;106:240–254.)

embryonic heart, the atrial myocardium is contiguous with the myocardium of the ventricles throughout the AV junction (67). At these stages, the physical insulation by fibrous tissue is not essential because of the intrinsic property of slow propagation of the cardiac impulse by the AVC myocardium (24,87). In the septating heart, the AVC myocardium is sandwiched between the epicardially derived tissues of the AV groove at the epicardial side, and the endocardially derived AV cushion at the endocardial side (94). Due to the growth of the ventricular and atrial chambers, the significant thickening of the free walls of the ventricles, particularly at their bases, and the relatively slow proliferation of the AVC myocardium, the connective tissue of the AV grooves becomes invaginated between the atrial and ventricular myocardial masses, creating the mesenchymal insulation plane (Fig. 14.14). The molecular mechanisms driving the fusion of the epicardially derived tissue with the AV cushions, which finalizes the AV insulation, are not fully understood, but an essential role of epicardially derived cells in this process is well established (95).

With exception of the muscular connection through the bundle of His, the AV myocardial continuity is essentially interrupted at approximately 12 weeks of human development (67). In the fetal and early neonatal human heart, however, multiple tiny myocardial strands have been observed crossing the otherwise fully formed plane of AV insulation (15,96). Persistence of these remnants of the AVC musculature was suggested to be the substrate for electrical preexcitation of the ventricles, which may result in the Wolff-Parkinson-White syndrome, the most prevalent type of supraventricular tachyarrhythmias in children (97). An important characteristic of these bundles is their high conductivity due to the expression of fast-conducting connexin 43 (98), which can lead in specific circumstances to life-threatening arrhythmias. The myocardial

strands found in normal neonatal hearts, however, are derived from the AVC, and our own studies, as yet unpublished, suggest they retain the AVC phenotype and are negative for connexins 40 and -43, making it unlikely that the mere failure of their disappearance is sufficient to explain the phenomenon of ventricular preexcitation with rapid AV conduction.

The Bmp-receptor 1a, also known as *Alk3*, and the transcription factor *Tbx2* have been shown to play an important role in the correct formation of the plane of insulation on the left side of the mouse heart (79,99). In the absence of myocardial *Alk3* or *Tbx2* expression, not only does connective tissue fail to form between the atrial and ventricular chambers, but also the persisting myocardial strands become fast conducting, and are thus capable of causing preexcitation. The formation of accessory pathways with fast conduction properties, therefore, involves both abnormalities in the development of the fibrous insulation *and* the differentiation of the originally slow-conducting AVC myocardium into fast-conducting working myocardial phenotype.

The bundle of His, which remains the only muscular connection between the atrial and ventricular chambers after completion of the formation of the insulation plane, becomes gradually isolated from the myocardium of the ventricular septum by a connective tissue sheath originating, most probably, from the epicardially derived tissues of the AV grooves. In fetal hearts, the cardiomyocytes of the AV node and bundle of His remain in contact with the myocardium of the ventricular septum (Fig. 14.15). Persistence of these connections between the AV node (or bundle of His) and the ventricular myocardium during further maturation in the fetal period may constitute the slow-conducting substrate of one of the variants of so-called Mahaim-type reentry tachycardia, although similar slow-conducting AV connections can be demonstrated along the entire right AV ring, likely representing persisting remnants of the AV ring tissues (16).

Figure 14.12. Lineage analysis of the developing atrioventricular (AV) node in the mouse heart. **Panel A** and **B** schematically demonstrate the methodology utilized to follow the fate of cells in vivo. In mouse line I the transgene *Cre* (Causes a recombination event) is introduced under the direction of a tissue-specific promoter. Another transgenic mouse line (II) holds a construct consisting of a promoter, which is active in all body cells, and the reporter gene (here the bacterial gene *LacZ*, but it can also be *EGFP*), expression of which is prevented by the STOP sequence (depicted by) upstream of the reporter gene. This STOP sequence is flanked by so-called *loxP* sites, which are recognized by the enzyme *Cre*. When both mice are crossed, the STOP sequence is irreversibly removed in all cells where *Cre* is expressed, by which the reporter gene is then activated in the original cells and their offspring. Subsequently these cells can be labeled by staining for the reporter gene (blue cells in **panel B**), even when the endogenous gene driving *Cre* expression is no longer active. This technique makes it possible to study the origin of the cells of the different components of the mature mammalian four-chambered heart. (Modified from Horsthuis T et al. Can recent insights into cardiac development improve our understanding of congenitally malformed hearts? *Clin Anat* 2009;22:4–20.) Such a study was performed to assess the developmental origin of the AV node, where several tissues have been suggested to contribute, including the myocardial wall of the coronary sinus and the dorsal mesenchymal protrusion, or vestibular spine. **Panel C** shows the AV plane of insulation with the AV rings, the AV node and AV bundle. The dashed line shows the plane of sectioning through the AV node of the postnatal mouse heart shown in **(D)** and **(E)**. The compact atrioventricular node (cavn) is not stained and remains free of recombination, when the *Tbx18* (**panel D**) or *MEF2c* (**panel E**) promoter is used to drive *Cre* expression. This implies that neither the sinus muscle, which is marked by the expression of *Tbx18*, nor the myocardium derived from the dorsal mesenchymal protrusion (dmp-d), which expresses the *MEF2c* enhancer contributes to the AV node, lending no support to the hypothesis that coronary sinus or dorsal mesenchymal protrusion-derived myocardium contribute to the formation of the AV node. Instead the entire AV bundle, along with the so-called lower nodal cells, is derived from ventricular myocardium. avb, atrioventricular bundle; cs, coronary sinus; EGFP, enhanced green fluorescent protein; expr, expression; lv, left ventricle; pv, pulmonary vein; ra, right atrium. (Modified from Aanhaanen WT, Mommersteeg MT, Norden J, et al. Developmental origin, growth, and three-dimensional architecture of the atrioventricular conduction axis of the mouse heart. *Circ Res* 2010;107:728–736.)

DEVELOPMENT OF THE VENTRICULAR CONDUCTION NETWORK

In the postnatal heart, the electrical impulse, after being delayed in the AV node, is transmitted via the ventricular conduction network consisting of the bundle branches and Purkinje fibers.

The main function of the ventricular conduction network is the rapid propagation and uniform distribution of the impulse to the ventricular muscle mass. The fast-conducting properties of the ventricular conduction system (VCS) are due to the high expression of connexins 40 and 43— proteins, which form gap junctions with high conductance properties (100). As with the ventricular working myocardium, the cardiomyocytes

Figure 14.13. Three-dimensional and molecular analysis of the developing AV conduction system in the developing human heart. Panels A and D show a four-chamber cut through the 3-D models of the human embryonic heart with incomplete (stage 16) and complete (stage 23) septation, upon which the expression of the conduction system marker TBX3 was projected (shown in green). TBX3, which represses myocardial differentiation, marks the tissues that will retain their primitive phenotype and will develop in part into the conduction system of the heart. Histological sections taken through the dorsal part of the AV canal were stained for the fast-conducting gap-junctional proteins connexin40 and -43 (panels B and C). The TBX3-positive myocardium of the developing AV node lacks expression of these connexins (arrow). At later stages the domains of TBX3 expression already resemble the postnatal configuration of the AV system. The AV node primordium (outlined by the dashed line in panels E and F) does not express connexins 40 and 43, being a slow conducting structure. 3-D, three-dimensional; AVC, atrioventricular canal; cor, coronary; LA/RA, left/right atrium; LV/RV, left/right ventricle; rrv, right venous valve. (Modified from Sizarov A, Devalla DH, Anderson RH, et al. Molecular analysis of patterning of conduction tissues in the developing human heart. *Circ Arrhythm Electrophysiol*, 2011;4:532–542.)

of the postnatal VCS are specialized in fast conduction. Unlike the working myocytes, however, they have a poorly developed contractile apparatus, and even display some degree of automaticity, resembling the embryonic primitive phenotype (61). In embryonic hearts that do not have discernable bundle branches or a Purkinje fiber network, fast conduction within the developing ventricles already is present at stages when the trabeculations just have appeared. It has been established that the development of the mature pattern of ventricular activation and formation of the Purkinje fiber network are closely related to the development of the ventricular trabeculations (65). The cavities of the ventricles in the early embryonic heart contain an extensive meshwork of trabeculations attaching to the thin outer ventricular wall, which, similar to the trabeculations, expresses the fast-conducting connexins 40 and -43 (31,80,101). Thus, there is a molecular substrate for the preferential rapid conduction of the electrical impulse through the ventricular trabeculations to the ventricular musculature in the embryonic heart without a fully differentiated true ventricular conduction network.

During normal heart development, proliferation ceases in the trabeculations soon after their formation, while the outer ventricular wall becomes highly proliferative to form the compact myocardial layer (31,102), thus meeting the increasing demand to produce more powerful contractions. The newly formed compact layer of the ventricular wall, unlike the trabecular myocardium, does not express connexin 40. The extent of the trabeculations within the ventricular chambers does not change significantly during development compared to the enormous growth of the compact layer (Fig. 14.16). This suggests that failure of proper formation of the compact ventricular wall and abnormal continuing growth of the trabecular layer are responsible for the so-called noncompaction cardiomyopathy, where the extensive trabecular network coexists with a compact layer of decreased thickness (103).

The observation that so-called Purkinje myocytes along with myocardial markers also express markers reminiscent of neuronal cells has resulted in much debate about the origin of the ventricular conduction system. Most of the data

Figure 14.14. Early stages of the formation of the AV plane of insulation in the human heart. These photomicrographs show the right part of the AV canal in a stage 16 heart and the right AV junction in later stages. Sections were immunohistochemically stained for the myocardial marker troponin I (shown in blue). The asterisk points to the subepicardial mesenchymal tissue accumulated in the AV groove. At stage 16, atrial and ventricular myocardium are contiguous through the AV canal musculature (arrow in panel A). This continuity is markedly reduced already two stages later (arrow in panel B). Note, that at the latest embryonic stage there are still myocardial fibers connecting the atrial myocardial with the ventricular wall (arrow in panel C). CS, Carnegie stage; RA, right atrium; RV, right ventricle.

regarding the induction of the VCS have come from studies in chicken embryos, where fate-mapping experiments have unequivocally demonstrated that the entire conduction system has a myocardial origin (65). Individual ventricular myocyte precursor cells give rise to a series of progeny that migrate preferentially vertically to form the meshwork of trabeculations (104, our unpublished observations). From mouse studies, it is known that neuregulin-1 and Notch signaling are necessary and sufficient, to form the ventricular trabeculations through regulating the relative proportion of the embryonic ventricular cardiomyocytes that form the trabecular and compact myocardium (105,106). Another signaling molecule, endothelin-1, secreted by endocardial cells

covering the ventricular trabecular myocardium, probably in response to increasing biomechanical forces such as shear stress and pressure in the walls of the ventricular chambers, has been shown to play an important role in the induction of the Purkinje fiber network in the chicken embryonic heart (107,108). Current models of the development of the ventricular conduction network involve neuregulin signaling-mediated induction and formation of ventricular trabecular myocardium and endothelin signaling-mediated differentiation of subendocardial myocytes into Purkinje myocytes (61,65,109) (Fig. 14.17), with recent lineage studies in the mouse supporting a biphasic mode of formation of the VCS (110).

Figure 14.15. Histological and molecular analysis of the AV node in the early human fetus. Serial sections of a 13 week fetal heart were stained using Masson's trichrome (panel A) and immunohistochemistry for TBX3 and the myocardial marker troponin I. Note the tiny myocardial tracts still crossing the forming plane of insulation (arrows). These myocytes are positive for the conduction system marker TBX3 and are, thus, the remnants of the embryonic conduction tissues. AV, atrioventricular; TnI, troponin I.

Figure 14.16. Development of the compact ventricular myocardial wall and the Purkinje system in the human heart. Histological sections through the left ventricular free wall were double stained for troponin I (shown in blue) and connexin40 (shown in pink). In the ventricles at Carnegie stages (CS) 12 through 15 connexin40 is expressed transmurally and no overt compact layer is present. After stage 15 the connexin40-negative compact layer of the ventricular wall forms and expands at the epicardial side. Note that the thickness of the trabecular component of the ventricular wall remains the same between stages 15 and 23 (yellow arrows). At the end of the embryonic period connexin40 becomes confined to the trabecular myocardium only, whereas the compact layer in the late normal fetal heart expands considerably (panel E). Note, that in the infant heart with left ventricular “noncompaction” (panel F) the compact layer of the ventricular wall is underdeveloped, while trabecular layer is abnormally expanded. (Modified from Freedom RM, Yoo SJ, Perrin D, et al. The morphological spectrum of ventricular noncompaction. *Cardiol Young* 2005;15:345–364.)

DEVELOPMENTAL ASPECTS OF CARDIAC ELECTROPHYSIOLOGY

A great variety of ion channels, connexins, and calcium-handling molecules determines the different properties of the action potential in the various types of myocytes in the heart (111). The action potential and the rapid changes in voltage differences across the cell membrane are determined by shifts in intra- and extracellular concentrations of several ions, including sodium, potassium, and calcium. Such shifts in ionic concentrations are achieved through active and passive flows of the ions through the different channels, ion pumps, and gap junctions, together constituting the ion currents. Action potentials have a number of characteristics, such as the upstroke velocity, which is the speed of membrane depolarization; the duration, this being the time from the initiation of depolarization to complete repolarization of the cell membrane; the amplitude, in other words the extent of decrease of the negative membrane charge; and the so-called plateau phase, which is the period of relative stability during the membrane depolarized state. The different types of cardiomyocytes display distinct action potential characteristics (Fig. 14.18). During development and maturation of the heart, dramatic changes occur in these characteristics (112,113), affecting myocardial conduction and

refractoriness properties, which, in turn, influence the physiologic function of the maturing heart.

Pacemaking in the Maturing Heart

In the early embryonic heart, all cardiomyocytes are capable of generating the electrical impulse, albeit with gradients of pacemaking dominance, decreasing from the venous to the arterial pole (38,46). In chicken embryos, the earliest activation has been recorded in the systemic venous sinus and both atria (114). Later in development, the origin of the electrical impulse becomes confined to the region of the sinus node. In the immature postnatal heart, nonetheless, there are considerable shifts of the primary pacemaking site over a much wider area than that occupied by the morphologically recognizable sinus nodal cells (115). Down- and upregulation of several ion currents in the adult sinus nodal and atrial working myocardial cells are required to allow a small SN to drive the depolarization of a large mass of atrial chamber myocardium (116). The high expression of HCN4, the ion channel responsible for the pacemaker “funny” current, and Cav3.1, the T-type voltage-gated calcium channel, are essential in the spontaneous depolarization process. Equally important is the

Figure 14.17. Schematic model for the development of the ventricular trabeculations and Purkinje fiber network. At early stage of chamber formation the ventricular wall is 3 to 4 cell thick and only tiny trabeculations are present. Neuregulin-1 (NG1) and Notch1 play important roles in the induction of the formation of extensive meshwork of trabeculae in the consecutive stages. The endothelial cells (endo) then signal, via endothelin-1 (ET-1) and endothelin converting enzyme (ECE-1), to initiate the induction and maturation of the ventricular conduction system (VCS), where transcription factor Nkx2-5 also plays an important role. Expression of connexin40 and other VCS markers is depicted in a gradient from red (high) to gray (no expression). Epi indicates epicardium. Cx40, connexin40; CS, Carnegie stage; ECE-1, endothelin converting enzyme 1; E, embryonic day; endo, endocardium; epi, epicardium; ET-1, endothelin-1; NG1, neuregulin-1; VCS, ventricular conduction system. (Modified from Christoffels VM, Moorman AF. Development of the cardiac conduction system: why are some regions of the heart more arrhythmogenic than others? *Circ Arrhythm Electrophysiol* 2009;2:195–207; Mikawa T, Hurtado R. Development of the cardiac conduction system. *Semin Cell Dev Biol* 2007;18:90–100; and Wagner M, Siddiqui MA. low expression, or virtual absence, of the fast-conducting connexins 40 and 43, of the inward-rectifying potassium channel Kir2.1, and of the sodium-channel Nav1.5. These latter currents are responsible, respectively, for the stabilization of the membrane resting potential and its rapid upstroke in the cardiomyocytes of the atrial and ventricular chambers (43,115). The establishment of sharper borders between the domains of expression of these functional proteins likely is responsible for the progressive confinement of the site of pacemaking to the sinus nodal region of the heart. The timing of changes in the expression of these ion channels in the human maturing heart is not yet characterized. Our preliminary results from studies in late embryonic and early fetal human hearts indicate that there is a gradual decrease of HCN4 expression in the myocardium of the atrium, the pulmonary and systemic venous sleeves, and the AV junction, with subsequent confinement and strong expression of HCN4 to the developing SN (Fig. 14.19). Failure of downregulation of the expression of HCN4 in these structures during later stages of development may provide a substrate for arrhythmogenic ectopic foci in the postnatal heart.

Propagation of the Electrical Impulse in the Atrial Myocardium

After generation of the impulse and breakthrough from the sinus node, the electrical impulse spreads rapidly and uniformly over both right and left atrial chambers as a broad wave front (117),

which is reflected in the P wave of the surface electrocardiogram (118). Conflicting interpretations of studies from the beginning of the previous century on the conduction of the heart beat from the SN toward the AV node (119) stimulated extensive research aimed at discovering “specialized” internodal pathways for the preferential conduction of the impulse between the two cardiac nodes (120,121). Histologic studies failed to identify the presence of distinct insulated myocardial tracts within the atrial musculature (20), while functional studies have provided evidence that anisotropy, or unidirectional orientation of the atrial muscle fibers, is responsible for the slightly faster conduction within some areas of the atrial musculature (19,122). In the embryonic heart, nonetheless, it is possible to recognize molecularly distinct pathways within the developing RA that extend from the sinus nodal primordium toward the developing AV node (Fig. 14.20). The cardiomyocytes making up these “tracts” express the transcription factor Tbx3 and neural tissue antigen HNK-1, both considered to represent markers of the conduction system (123,124) (though expression of HNK-1 was found also outside the developing conduction system) (124,125). It is likely that remnants of the Tbx3- and HNK1-positive areas of the primary myocardium in the postnatal heart are the substrates for abnormal automaticity that result in ectopic atrial tachycardias seen in children. Paroxysmal atrial fibrillation, originating from the myocardial sleeves of the pulmonary veins, is more prevalent in adults, and developmentally unrelated.

Age-related changes in the functional and cellular electrophysiologic properties of the atrium are well recognized. In rat and dog atrial myocardium, action potentials recorded in

Figure 14.18. Cellular electrophysiology of the cardiac conduction system of the adult human heart. **Panel A** shows schematically the location of the components of the human pacemaking and conduction system, while **panel B** shows the schematic representation of the action potentials in the different cardiomyocytes. Note, that the slowly conducting sinus (S) and atrioventricular (AV) nodes have a distinct morphology of the action potential as compared to the action potentials from the rapidly conducting chamber myocardium, bundle branch and Purkinje fibers. The nodal action potential is characterized by a slow upstroke velocity (phase 1 in the right-sided **panel C**), relatively high (i.e., less negative) resting membrane potentials of about -60 mV, the absence of the plateau phase, and spontaneous depolarization during phase 4. The action potential of the atrial and ventricular chambers, bundle branches and Purkinje fibers (left-sided **panel C**) is, in turn, characterized by the low and stable resting membrane potential of about -90 mV, very rapid upstroke velocity, and presence of the plateau phase (2) during relatively stable depolarized state of the cardiomyocyte membrane. Both types of action potentials have the phase of rapid repolarization (phase 3), during which the potential of the membrane returns to its resting value. The action potential is longest in the Purkinje fibers and shortest in the atrial cardiomyocytes. **Panel C** depicts also the ionic currents (designated as I), which are responsible for the depolarization or repolarization phases of the action potential: $I_{Ca-L/T}$, L- and T-type calcium current; I_f , “funny” current; I_{K1} , inward-rectifier potassium current; $I_{Kr/Ks}$, rapid- and slow components of delayed-rectifier potassium current; I_{Na} , sodium current; I_{to} , transient outward potassium current. AV, atrioventricular; ECG, electrocardiogram; S node, sinus node.

newborn animals are characterized by a shorter plateau phase and duration than in older animals (126). Very limited data exist concerning the maturation of these electrophysiologic characteristics in the developing human heart. In the early human fetus, from 12 to 16 weeks of gestation, action potentials recorded from atrial and ventricular myocardium are comparable with those in the adult, and by mid-gestation conduction velocities are only slightly slower than those in the adult heart (93,127,128). Increasing action potential plateau and duration as a function of age have also been observed in atrial myocardium of the human postnatal heart (129). Shorter atrial refractory periods due to the shorter action potential durations (APDs) in the immature atrium may facilitate the conduction of very closely coupled

impulses, and could render the newborn atrium more susceptible to intraatrial reentry (130,131) (Fig. 14.21). This partly may explain the occurrence of atrial arrhythmias such as atrial flutter in the otherwise healthy fetus or newborn infant (132).

Physiology of the Maturing AV Conduction System

As we have emphasized, a delay in conduction between the atrium and ventricle can be observed already in the early chamber-forming chicken heart. Action potentials recorded from the AVC myocardium of such young embryonic hearts exhibit a characteristic low upstroke velocity and long duration (24,87),

Figure 14.19. Expression of the pacemaker channel HCN4 reflects the progressive maturation of the differentiating myocardium in the human heart. Histological sections of human embryonic and fetal hearts were immunohistochemically stained to show the expression of the pacemaker ion channel HCN4 (depicted in green), which is responsible for the spontaneous depolarization of the nodal cells. In the relatively early embryonic heart (panel A) HCN4 is broadly expressed, in the systemic venous tributaries, atrial chambers and AV canal, but not in the ventricular chambers. In the late embryonic heart (panel B), HCN4 expression declines in the atrial walls, but remains high in the venous and coronary sinus, and AV junctions. Note, the weak expression of HCN4 in the walls of the pulmonary veins. In the early fetal heart (panel C) HCN4 expression at the venous pole is present only in the sinus node, not in the atrial walls or pulmonary vein myocardial sleeves. AVC, atrioventricular canal; cor, coronary; LA/RA, left/right atrium; LV/RV, left/right ventricle; mvo, mitral valve orifice; pulm, pulmonary; SV, sinus venosus.

Figure 14.20. Presence of the internodal “tracts” in the human embryonic heart. Panel A shows a 3-D reconstruction of the expression of neural tissue antigen HNK-1 shown in red for the atrial part and in gray for the AV part of its expression domain in a stage 18 human embryonic heart. The view is from the right after removing the lateral part of the RA. Three HNK-1-positive “tracts” are present running from the SN primordium (SN-prim) toward the AV node primordium (AVN-prim), but not connecting with the developing AV node. These three HNK-1-positive “tracts” run in the right venous valve (1), in the left venous valve (2), and in the spurious septum and ventral wall of the RA (3). The last “tract” converges with the so-called retroaortic node region dorsal to the OFT. (From Blom NA, Gittenberger-de Groot AC, DeRuiter MC, et al. Development of the cardiac conduction tissue in human embryos using HNK-1 antigen expression: possible relevance for understanding of abnormal atrial automaticity. *Circulation* 1999;99:800–806, with permission.) Panel B shows a 3-D reconstruction of the expression of the transcription factor TBX3 (shown in green) in a stage 16 human embryonic heart. The view is from the right with the myocardium (gray) made transparent. There are also three “tracts” of TBX3-positive myocardium identifiable, running in the right venous valve (1), in the leading edge of the atrial septum (2) and in the spurious septum and ventral wall of the RA (3). The TBX3-positive “tracts” are, unlike the HNK-1-positive tissues, in direct continuity with the developing AV node region. AS, atrial septum; AVN-prim, atrioventricular nodal primordium; CS, coronary sinus; ICV, inferior caval vein; LSCV/RSCV, left/right superior caval vein; LV/RV, left/right ventricle; OFT, outflow tract; SN-prim, sinus nodal primordium.

Figure 14.21. Developmental aspects of the conduction through the atrial myocardium. **Panel A** shows action potentials recorded from morphologically similar sites along the terminal crest (depicted by 1 and 2 in the left-sided photo of the opened right atrium) in adult and newborn dogs. In contrast to the adult, neonatal atrial potentials have little or no plateau phase and are significantly shorter in duration. (Modified from Anderson RH, Cook AC. The structure and components of the atrial chambers. *Europace* 2007;9:vi3-vi9; and Spach MS et al. Multiple regional differences in cellular properties that regulate repolarization and contraction in the right atrium of adult and newborn dogs. *Circ Res* 1989;65:1594-1611.) **Panel B** shows how the introduction of a premature extrastimulus (S₂) to the RA of a newborn dog (during gentle vagal stimulation, RVS) results in the induction of a long train of atrial fibrillation/flutter. Similar but shorter runs of atrial fibrillation/flutter can be induced in the absence of vagal stimulation. Such repetitive responses become less common at older ages. HRA, high right atrium; RVS, right vagal stimulation train; ECG, electrocardiogram lead II; ICV, inferior caval vein; Pect, pectinated; S₁, S₂, paced stimuli; SCV, superior caval vein; Theb.v, Thebesian valve. (Modified from Pickoff AS, Stolfi A. Modulation of electrophysiological properties of canine heart by tonic parasympathetic stimulation. *Am J Physiol* 1990;258:H38-H44.)

which are the electrophysiologic characteristics reflecting slowing of conduction. AV delay, including Wenckebach's periodicity, also has been described in the embryonic rat heart prior to formation of the AV conduction system (133). In the embryonic rat heart, acetyl cholinesterase can be detected in the myocardium adjacent to the endocardial cushions, but not in the free walls of the atria and ventricles (134). This may indicate that a cholinergic mechanism is already in some manner linked to the AV delay observed at these early developmental stages, when the heart is not yet innervated.

Individual cardiomyocytes have different types of contact with each other. One type of contact consists of the so-called gap junctions. Gap junctions are highly specialized protein channels that connect adjacent myocytes and allow the passive passage of electrical current, or the flow of charged ions, via a low-resistance pathway from one cell to the next (135). The connexons making up the gap junction may consist of different types of connexins, which vary in their conductivity. Expression of different connexin isoforms results in gap junctions with differing conduction properties. In the early fetal human heart, both the AV node and bundle of His, as well as the lower rims of the atrial chambers, do not express the fast-conducting connexins 40 and 43, which is reflected in their slow conduction (our unpublished observations). This explains the AV delay and absence of ventricular pre-excitation in the setting of incomplete formation of the fibrous annulus and the fibrous sheath of the bundle of His (93). The refractory period of the AV junction in the human fetal heart, moreover, is significantly longer than that of the ventricular

myocardium, thus protecting the ventricles from being excited by supraventricular impulses in its vulnerable period (93). During later fetal stages, concomitant with the fibrous insulation of the bundle of His from the myocardium of the ventricular septum cardiomyocytes making up the bundle upregulate the expression of connexin40, changing it to a rapidly conducting structure. In human hearts, however, this does not affect the PR interval of the fetal magnetocardiogram, which remains unchanged between the 20th and 42nd gestational weeks (136).

In the postnatal heart, important differences in electrophysiology and morphology of the AV junction have been reported between children and adults. Routine histology has shown that the inferior extension of the AV node is much smaller in neonatal and infant hearts when compared to the adult (137). In human and canine young hearts, the antegrade AV refractory periods (the time when no transmission of the electrical impulse is possible) are typically shorter, and intact retrograde, or ventriculoatrial, conduction is more common (138,139). In contrast, cellular electrophysiologic studies of the AV node in neonatal and adult rabbits have shown no significant differences in action potential characteristics, resting AV nodal conduction times, or Wenckebach intervals between the two age groups (140). It also has been reported that, in calf, goat, and pig newborn hearts, the AV node lacks the ability to function as an effective filter of very rapid or premature beats, resulting in very fast conduction and ventricular fibrillation (141-143). Species differences, therefore, may exist in the degree of postnatal maturation of AV nodal function.

In young children, there is a much lower incidence of the so-called dual AV nodal physiology and AV nodal reentry tachycardia as compared to adults (144,145). Dual physiology of the AV node involves two functionally distinct myocardial pathways through the node, the so-called fast and slow pathways, which are currently thought to be the main substrates for AV nodal reentry tachycardia (146).

Developmental Aspects of the VCS and Working Myocardium

The conduction velocity in the synchronously contracting ventricular chambers of the septating heart has been estimated to be more than ten times faster than in the primary myocardium of the looping heart tube (24,87,133). It has been shown that the “mature” apex-to-base activation pattern of the ventricles is present in the embryonic rabbit heart prior to the completion of ventricular septation (147). As we have already discussed, there is preferential conduction through the ventricular trabecular myocardium due to the high expression of the fast-conducting connexins. The morphology and gene expression patterns of the developing ventricular chambers are very similar in the rabbit, mouse, chicken,

and human, suggesting conservation of the electrical activation pattern between these species. The critical role of expression of connexins during development for normal conduction is demonstrated by the abnormal, often lethal, disturbances of cardiac conduction observed in transgenic mice with deficiencies of these specific connexin isoforms (148,149). In the developing chicken and rat heart, cellular electrophysiologic changes in myocyte action potential characteristics of working myocardium promote an increase in conduction velocity with maturation. Increases in the upstroke velocity and amplitude of the action potential in the ventricular cardiomyocytes, and therefore ventricular conduction velocities, have been noted in both species during embryonic development (150,151). These changes may be the result of the switch from slow to fast sodium ion channels, responsible for the rapid upstroke phase (152), and the increase of the resting membrane potential, which also contributes to a higher action potential upstroke velocity. The developmental aspects of the maturing Purkinje fiber network mainly have been described in fetal and young postnatal canine hearts. Age-dependent increases in action potential upstroke velocity, amplitude, resting membrane potential, and duration have been described. In addition, changes in the ultrastructure of the developing canine Purkinje myocytes, including changes in cell shape, increases in cross-sectional area, and the development of intercalated discs and desmosomes undoubtedly contribute to the increase in conduction velocity noted with maturation (153–155). There are no data on the functional maturation of the Purkinje network in the human beside morphologic analyses in the mid-gestation fetal hearts (156).

Protection against rapid ventricular rates also depends in part on electrophysiologic properties of the conduction system at sites distal to the AV node. In the adult dog, APDs increase along the length of the Purkinje system, with the longest duration occurring just proximal to the site of subendocardial insertion, which functions as a physiologic gate that offers protection against closely coupled impulses. This electrophysiologic gate is not functional in the newborn heart, since nearly uniform APDs are recorded along the entire length of the Purkinje system (157) (Fig. 14.22). This could render the neonatal ventricular myocardium vulnerable to closely coupled impulses that might arise distal to the AV node.

Figure 14.22. Developmental aspects of the conduction through the Purkinje fiber network. Action potentials were recorded at three separate sites along the VCS of the newborn and adult dog. Site 1 corresponds to the proximal right bundle branch, site 2 just proximal to the distal ramifications of the ventricular conduction system, and site 3 within the distal ramifications within right ventricle (RV). Note, that in the adult dog, the longest action potential duration (APD) is recorded at site 2. This abrupt increase in APD at site 2 functions as a physiologic gate, capable of blocking the conduction of closely coupled impulses to the ventricles. This abrupt increase in APD is not observed in the newborn canine heart (i.e., the physiologic gate is absent). (Modified from Myerburg RJ et al. Electrophysiological properties of the canine peripheral A-V conducting system. *Circ Res* 1970;26:361–378; and Unterreker WJ, Danilo P Jr, Rosen MR. Developmental changes in action potential duration, refractoriness, and conduction in the canine ventricular conducting system. *Pediatr Res* 1984;18:53–58.)

Figure 14.23. Localization of the SN in variations of arrangement of the atrial appendages. In the usual arrangement (atrial situs solitus), the SN is located at the junction of the superior vena cava and RA. The reverse occurs in atrial situs inversus (*mirror imaged*). In juxtaposition of the atrial appendages, the SN becomes displaced along the right atrial anterior wall. In right isomerism there are bilateral sinus nodes. In left atrial isomerism the SN is highly variable, being absent, displaced, and/or hypoplastic. (From Ho SY. Clinical pathology of the cardiac conduction system. *Novartis Found Symp* 2003;250:210–221, with permission.)

THE CONDUCTION SYSTEM IN CONGENITALLY MALFORMED HEARTS

While the majority of malformed hearts have more-or-less normal arrangements of the conduction system, there can be significant deviations from the norm (158,159). During late embryonic development of the heart, the spatial distribution of the conduction system markers *Tbx3* (123) and *GLN2/HNK1* (74,124) is reminiscent of the location of the definitive and “residual” components, the latter being the largely regressing components of the developing conduction system still seen in the postnatal heart.

Malposition of the SN may occur in left juxtaposition of the atrial appendages, where anterior displacement of the SN is observed; in right isomerism, where bilateral sinus nodes are formed; and in left isomerism, where a SN may not be identifiable (Fig. 14.23). In the setting of some congenital cardiac

malformations, there is considerable aberration in the course of the AV conduction axis (159), which can be explained well on the basis of knowledge of the developing conduction system. Incomplete formation of the RV, as seen in tricuspid atresia, double-inlet left ventricle, and straddling tricuspid valve represents incomplete rightward transfer of the right side of the AV canal. In these defects, the AV conduction system always is located at the junction of the inferocaudal aspect of the ventricular septum carrying the bundle of His, and the AV junction where the AV node forms. The position of the AV node and bundle of His is thus determined by the relative positions of the right and left ventricles, and the degree of underdevelopment of the right AV ring. In transposition of the great arteries with AV discordance, the AV node and bundle of His are located anteriorly (160). A similar analysis applies to the formation of the conduction system in the setting of AV septal defect with common AV junction (161) and other malformations (Fig. 14.24).

Figure 14.24. Disposition of the AV conduction system components in congenitally malformed hearts. In the setting of tricuspid atresia (panel A), the atrioventricular node (avn) is positioned on the floor of the blindly ended right atrium. The conduction system extends onto the crest of the muscular ventricular septum, coursing inferoposterior to the rim of the ventricular septal defect (VSD). In double-inlet left ventricle (panel B), the AV node and the bundle of His are positioned anteriorly, at the site where the right AV ring is in contact with the crest of the muscular ventricular septum, which separates the left ventricle from the outlet chamber (the incomplete right ventricle). In hearts with straddling tricuspid valve (panel C), the AV node and the bundle of His are positioned at the postero-inferior site along the right AV ring and its contact with the muscular ventricular septum. In AV septal defect with common AV junction (panel D), the AV node is positioned posteriorly and inferiorly outside the triangle of Koch, as the central fibrous body is absent. The relatively long bundle of His runs along the inferior rim of the muscular ventricular septum. In congenitally corrected transposition of the great arteries (cc-TGA, panel E), the AV node is positioned anteriorly near the atrial septum. The long bundle of His is related to the pulmonary OFT and runs in anterocephalad direction, passing anteriorly to the rim of the VSD, if present. LV/RV, left/right ventricle.

George F. Van Hare ■ Anne M. Dubin

In this era of easily available high-resolution imaging techniques, does electrocardiography (ECG) still have a place in the diagnosis and management of children with congenital heart disease? Certainly, for the noninvasive diagnosis of arrhythmias and cardiac conduction disorders, there is no substitute for careful analysis of the ECG. In addition to the assessment of arrhythmias, the ECG is important in the diagnosis and management of heart disease in children. Although rarely diagnostic of the type of congenital heart disease, the ECG should be thought of in the same way as the physical examination. It provides clues to the likely diagnosis, provides information about the severity of the condition, and may be indicative of other associated problems. Additionally, review of the ECG may identify important discrepancies as compared with the patient's presumed diagnosis, prompting further testing or a more careful review of the existing data. Most experienced pediatric cardiologists consider a cardiology consultation incomplete without a review of the ECG.

THE HISTORY OF ELECTROCARDIOGRAPHY

Although Augustus Waller was the first to record an ECG in a human (1), Willem Einthoven of The Netherlands is considered the father of electrocardiography. In 1901, Einthoven published a description of the string galvanometer, a device ideally suited for recording the rapidly changing and weak currents of cardiac electrical activity present on the body surface (2). During subsequent work, Einthoven identified the major waveforms of the ECG, and initially named them A, B, C, and D. He subsequently changed the naming system to P, Q, R, S, and T waves (Fig. 15.1), leaving room at either end of the alphabet for naming of new, as yet undiscovered, waves (as later came to pass when the U wave was described). The string galvanometer proved useful for the study of the ECG. The investigations of Einthoven and Sir Thomas Lewis dominated the early years of ECG studies, and they are credited with bringing the ECG to the bedside (3). This was not anticipated by Waller: "I certainly had no idea that the electrical signs of the heart's action could ever be utilized for clinical investigation" (1). Recordings in children followed, and Ziegler (4) reviewed the early reports on the use of the ECG in children. In 1913, Hecht published a "comprehensive" study, evaluating all three standard bipolar leads (I, II, III) in ECG tracings from hundreds of premature infants, term infants, and children with normal and abnormal hearts. By the late 1930s, the distinctive developmental changes that occur in the ECGs of normal infants and children had been described (4).

PRINCIPLES AND TECHNICAL CONSIDERATIONS IN RECORDING THE ELECTROCARDIOGRAM

The Scalar Electrocardiogram

The heart is an electrically active organ, and the current flows that result in cardiac contraction can be recorded from the body surface. How these electrical events are transmitted to the body surface is a complex topic and involves characteristics both of the heart as a current source as well as of the chest, which acts as a conductor (5,6). These characteristics change in the presence of congenital defects and other forms of cardiac disease as well as with normal growth and development.

The basic principle of the ECG is that electrical potentials generated by the heart can be accounted for by considering these electrical events to be equivalent to those generated by a dipole source in a homogeneous volume conductor (the equivalent dipole model). This concept has the limitation of seriously oversimplifying these events, especially in the assumption of homogeneity of conduction through the chest. The scalar ECG can be thought of as the record of voltage variation of this dipole with respect to time, in the particular orientation of the lead recorded. Cardiac electrical activity, of course, generates potentials in three dimensions, so any particular lead provides a very small amount of the potentially available information that can be recorded. For this reason, the conventional ECG includes 12 or 15 leads, arranged to give recordings along a variety of lead orientations to better represent the cardiac activity in three dimensions. The choice of these leads evolved as studies of the ECG progressed and, in retrospect, may not represent the best of all possible lead systems. However, these particular leads are deeply entrenched in modern cardiology practice.

Electrocardiographic interpretation begins with artifact-free ECG recordings. In addition to accurate electrode placement, cleaning of the skin with alcohol or acetone is essential to lower the skin resistance. ECG recordings in active infants and toddlers can be a technical challenge.

The standard ECG record consists of 12 leads recorded from nine body surface locations with the patient in the supine position (7). The ideal recorder should have the capability of displaying 3 to 12 leads simultaneously. The standard configuration usually is modified in children and adults with congenital heart disease, to record additional right (V3R, V4R) and left (V7) chest leads. Interpretation of rhythm disturbances ideally is accomplished by viewing a rhythm strip with 12 simultaneously recorded leads so that transient events, such as premature beats, can be assessed in all leads simultaneously.

Electrocardiograms can be recorded at various "paper speeds" and at various voltage standardizations (although

Figure 15.1. Scalar ECG showing P, Q, R, S, T, and U waves. The J point is shown, as well as the standard intervals (PR interval, QRS duration, ST segment, and QT interval).

modern systems acquire the tracings digitally and may be interpreted online without ever being printed on paper). Paper speeds of 12.5, 25, and 50 mm/s have been used, but 25 mm/s is standard. Standard ECG recording paper has major time divisions at 5-mm intervals and minor time divisions at 1-mm intervals. Therefore, at a paper speed of 25 mm/s, each large block corresponds to 0.20 seconds (200 ms), and 1 second is represented by five large blocks. Each small block represents 0.04 seconds (40 ms). In terms of voltage, full standardization refers to 1.0 mV/10 mm in vertical deflection on the recording, whereas half standardization refers to 0.5 mV/10 mm. It is important that the ECG reader always checks standardization prior to interpreting the ECG because the use of half standardization is common when large voltages cause overlap between leads. The choice of paper speed and gain may have an impact on the reproducibility of interval measurements (8). With the exception of the signal-averaged ECG, it is uncommon to discuss or report ECG voltages in terms of millivolts. It is much more common to discuss them in terms of millimeters of amplitude at full standardization. Therefore, for the remainder of this chapter, millimeters at full standardization is used rather than millivolts.

Vectorcardiography

Vectorcardiography was developed to correct some basic limitations of the conventional lead system and to display the data obtained by the ECG in a potentially more useful format. The dipole varies in magnitude and direction with time. The scalar ECG allows the presentation of the magnitude only, as it varies with time, and one needs to infer the direction of forces from the lead chosen. Each instant, the heart generates a force that has both magnitude and direction. This vector force changes with time and traces a loop during the duration of the QRS complex, which occupies all three dimensions. The vectorcardiography lead system allows a reasonably faithful representation of this three-dimensional loop as two-dimensional frontal, sagittal, and horizontal planes (Fig. 15.2). Several lead systems have been used. They each have their advantages and disadvantages. The Frank (9) system has been the most widely used, but the McFee system also has been used. The QRS vectorcardiogram, then, consists of a loop that starts at the beginning of the QRS, ends with the end of the QRS, and is displayed on paper in three planes.

Because of the need for special equipment, technical expertise, and the inconvenience of multiple leads, vectorcardiograms rarely are obtained in modern pediatric cardiology practice. Also, because of high-quality echocardiography,

Figure 15.2. Diagrammatic representation of a typical normal frontal plane vector loop (top left) with corresponding scalar ECG leads I, aVL, and aVF. The loop is clockwise in the frontal plane and lasts for 0.08 seconds. Each lettered segment corresponds to a portion of the QRS interval: a, 0 to 0.01 seconds; b, 0.01 to 0.03 seconds; c, 0.03 to 0.04 seconds; d, 0.04 to 0.055 seconds; e, 0.055 to 0.07 seconds; f, 0.07 to 0.08 seconds.

vectorcardiography has limited utility. Still, the best electrocardiographers think in terms of vectors even when interpreting the scalar ECG. Rather than memorizing patterns of QRS morphology and axis, they view the standard scalar ECG as a representation of the vector forces that vary with time, and perhaps understand the ECG better than those who simply “pattern read.”

Body Surface Mapping

A natural extension of the technique of ECG and vectorcardiography is the use of body surface mapping. To obtain the spatial-temporal representation of cardiac electrical potentials on the body surface, simultaneous measurement of potentials are needed at a number of sites (from 24 to 200) on the anterior and posterior torso. Several excellent reviews have addressed the specific details, including number and location of electrodes (10), electrode type (11), sample rate (12), digital collection and processing of ECG signals (13,14), and construction of maps (13). These techniques

are investigational and require specialized equipment and a high level of computerization. Recent developments in solving the "inverse problem" in electrocardiology have allowed for so-called electrocardiographic imaging in which epicardial potentials are computed from information available on the body surface. This approach has shown promise in the noninvasive evaluation of cardiac conduction abnormalities such as Wolff-Parkinson-White (WPW) syndrome and other electrical abnormalities of the heart (15).

Esophageal Electrocardiography

Because the esophagus normally is behind the left atrium and is in close proximity to the heart, an electrode placed in the esophagus will record atrial activity more locally than the standard ECG leads (16). This is especially useful in evaluating cardiac rhythm disturbances, particularly in situations where the P wave is difficult to find on the surface ECG (3). For example, when there is atrial flutter with 2:1 atrioventricular (AV) conduction, flutter waves may not be obvious on the surface ECG. Even if one observes atrial activity on the surface ECG, it may not be apparent that there are twice as many atrial deflections as ventricular deflections. The esophageal ECG solves this problem by recording atrial electrograms that are as large as or larger than the simultaneously recorded ventricular electrograms.

To obtain artifact-free esophageal ECGs, a soft bipolar electrode that has widely spaced large electrodes is used. Several are commercially available from 7 to 10 F in size. The catheter is positioned at the proper site and the signal filtered, usually employing band-pass filtering at 10 to 1,000 Hz, to eliminate the low-frequency respiratory artifact (16). Electrode placement is similar to nasogastric tube placement. The insertion depth for recording the maximum atrial deflection can be estimated from the patient's height (17,18). The ideal position is the site at which the atrial electrogram is about equal to the ventricular electrogram amplitude, and both are as large as possible. Positioning too distally will yield a large ventricular electrogram and a small atrial electrogram, and positioning too proximally will yield low amplitudes of both electrograms.

Signal-Averaged Electrocardiography

Under normal circumstances, the amplitude of P waves and ST segments is <2.5 mm, and T waves do not exceed 10 mm in the precordial leads. On the other hand, precordial R and S waves may have amplitudes of 30 to 40 mm. Interest in low-level potentials has led to the development of the signal-averaged ECG as a way of eliminating noise, which may exceed 0.03 mV peak to peak, and improving the signal-to-noise ratio.

The principal interest in the signal-averaged ECG has been to identify small high-frequency potentials either during the PR interval or during late QRS and ST segment (19). High-frequency potentials during the ST segment may result from areas of slow conduction that have been observed in myocardial infarction and associated ventricular arrhythmias (20). Interest in high-frequency potentials during the PR interval has focused on detecting depolarization within the His-Purkinje system.

The basic principle is that averaging a periodic, repetitive signal will reduce random noise to <0.001 mV, thereby enhancing the detection of low-amplitude signals. The signals are recorded at very high gain and are band-pass filtered. Waveforms usually are averaged over several minutes. Sensitivity and specificity of the technique for predicting adult patients at risk for ventricular arrhythmias have been reported. Reports of this technique for pediatric patients have been limited (21),

but it has been used to identify patients with arrhythmogenic right ventricular dysplasia (22).

24-Hour Ambulatory Electrocardiography

Named after Dr. N. J. Holter (23), the 24-hour ambulatory ECG, or Holter ECG, is an important tool in the diagnostic armamentarium of the pediatric cardiologist. It is used for various indications and is, perhaps, the most effective method to diagnose transient events such as AV block and other conduction disorders.

Modern Holter equipment records two or three channels of the ECG for 24 hours, either onto a cassette tape or digitally into a flash memory card in the recorder (24). The digital recording system has the advantage of being smaller and lighter and avoids the mechanical problems of cassette tape drag and damaged tapes. The ECG leads chosen for recording generally are modified chest leads and most closely resemble leads V1 and V5. The ECG is obtained using chest leads that are applied after adequate skin preparation, and the chest is often wrapped in an elastic bandage. The recorder can be worn on the belt, placed in a backpack, or suspended from a strap. The recorders have a digital clock for linking events with actual times, as well as a patient-activated event marker that allows the patient to annotate episodes of cardiac symptoms.

The recording is scanned using a computerized analysis system that provides both a full disclosure of the entire recording, as well as summary data regarding average, maximum, and minimum heart rates. Computerized algorithms allow the identification, characterization, and enumeration of premature atrial and ventricular contractions, as well as higher grades of ectopy and episodes of abnormal tachycardia. The patient keeps a diary of events while wearing the Holter recorder, and any such episodes of interest can be printed out and evaluated as part of the scanning process. The algorithms for arrhythmia diagnosis are limited in their applicability to pediatric patients, and the technician who scans and prints the report must be experienced in pediatric Holter scanning and supervised by a pediatric cardiologist (25–27).

Transtelephonic Event Recording

One limitation of Holter monitoring is that to record a transient symptomatic event, the event must occur spontaneously during the period that the patient is wearing the recorder. Thus, Holter monitoring often fails to record such events when they do not occur many times per day. Accordingly, to capture a symptomatic event, transtelephonic event recording allows longer periods of monitoring in a cost-effective manner (28,29). Several types of recorders are available. The simplest is a small device that records a single ECG channel for 30 to 60 seconds into the memory of the device when a button is pushed. It may have electrodes built into the device that contact the chest, or can be attached to the patient by several ECG electrodes or by wrist electrodes. These recorders have the disadvantage that the episode must be long enough for the recorder to be applied. This problem can be minimized by using a recorder that resembles a wristwatch, does not require additional electrodes, and can be worn continuously. An alternative to this simple type of recorder is the so-called memory-loop recorder. This recorder resembles a small Holter recorder, is attached to the patient by means of chest electrodes, and is worn continuously. Rather than recording and storing all the ECG data while worn, the device temporarily stores about 60 seconds of ECG data. When the patient experiences a symptom, he or she presses a button on the unit, causing it to store the 30 seconds of data that occurred prior

to pressing the button as well as a short amount of data following the episode.

The recorder stores the episode as an oscillatory audio signal. After an episode is captured by the recorder, the patient or a parent can transmit the ECG by playing back the stored audio signal over the telephone to the monitoring center, where the ECG is converted back to an ECG waveform and printed out for interpretation.

Also available are implantable loop recorders (ILR), which are implanted in the subcutaneous tissue on the chest wall and are active for up to 3 years. The device incorporates a continuous loop recording of the heart rhythm that is stored when the device is activated by the patient or parent. There is also an autoactivation component that allows the device to automatically record rhythms that are out of a preset range. Remote monitoring is available so that patients can transmit recorded data over phone lines using equipment at home (30). This device is useful for pediatric patients with syncope and/or palpitations (31). These are ideal when noninvasive methods have failed to document the rhythm particularly in cases of very infrequent events.

HOW TO READ A PEDIATRIC ELECTROCARDIOGRAM

An organized approach to evaluating the ECG is important to avoid failure to consider each characteristic of the ECG. Many advise that these characteristics be evaluated in a particular order, for example, by assessing the P wave first, the QRS second, and so on. The order, of course, is less important than a careful review of all the aspects of the recording (Table 15.1). Often pediatric ECGs are interpreted in light of extensive knowledge of the patient's condition. Clearly, the more information the reader has about the patient's condition, the more relevant the ECG interpretation will be. However, one often reads ECGs with no clinical information except the patient's age. For this reason, the ECG is considered a laboratory test. ECG attributes (e.g., intervals, voltages) are distributed within

a population. Thus, the prevalence of an abnormality depends on the normal cutoff points one picks. Just as the presence of a murmur does not necessarily mean that a patient has valvular stenosis, an "abnormal" ECG does not necessarily mean that the patient has heart disease. An example of this pitfall is the presence of a chest deformity (e.g., pectus excavatum or scoliosis) about which the ECG reader may not have information and needs to interpret the ECG. Even if the reader knows about the deformity, he or she may not know what constitutes normal for such a situation.

Pediatric ECG features are age dependent (Table 15.2). The PR interval, ST segment, and T wave are heart rate dependent as well. The most comprehensive tabulation of age- and heart rate-dependent ECG measures was provided by Davignon et al. (32,33).

The zero-voltage baseline, which is the reference level for ECG voltage measurements, is based on the fact that no potential differences exist on the body surface at that instant. At slow heart rates, the T-P or U-P interval is a good approximation of the voltage baseline. At faster heart rates, the P wave may be superimposed on the previous T-U wave. In this situation, the PR segment is the best alternative. When measuring a large deflection, choice of baseline selection is relatively unimportant. However, when measuring a low-level potential (e.g., ST segment), or attempting to determine onset of a waveform (e.g., QRS), choice of the baseline is critical—maybe as important as the measurement of interest.

Detailed descriptions of arrhythmia diagnosis are found elsewhere in this text. Likewise, the ECG patterns characterizing various forms of complex congenital heart disease are addressed in the chapters dealing with those diseases.

Rate and Rhythm

Ventricular Rate

Heart rate is determined by measuring the R-R interval. It often is more useful to think of cycle length than heart rate, because on the standard ECG there seldom is an entire minute's worth of heartbeats to count. Cycle length and heart rate have a reciprocal relationship. Cycle length (in milliseconds) is measured directly as the R-R interval. Heart rate is calculated by dividing the measured cycle length by 60,000 ms/min. Heart rate is highly dependent on age, body temperature, autonomic tone, and physical activity. For example, in a 14-year-old, a resting heart rate (cycle length) of 150 beats per minute (400 ms) would be abnormally high. However, it might be a perfectly normal rate for an apprehensive toddler during ECG recording. Similarly, a resting heart rate of 50 beats per minute (1,200 ms) in a healthy adolescent would be normal, whereas the same heart rate in an infant would signify bradycardia.

Origin of the Pacemaker

On most ECGs, there will be normal AV conduction with P waves preceding each QRS complex. It is important to determine if the P wave originates from the sinus node or elsewhere. The vector of a sinus P wave is from top to bottom and right to left (positive in leads I, II, and aVF). The P wave in sinus rhythm is biphasic in lead V1, initially being upright followed by a brief downward deflection. If the P wave does not have these characteristics, it does not originate from the sinus node and has an "ectopic" location. One must ascertain its origin, for example, a rhythm in which the P wave is inverted in leads I and aVL is termed a left atrial rhythm, whereas a P wave that is inverted in leads II, III, and aVF is termed a low right atrial rhythm (also known as a coronary sinus rhythm).

The rhythm may be regular, irregular, or regular with intermittent but predictable phases of irregularity. The last would

be a description of phasic sinus arrhythmia, which results from normal autonomic effects influences that mediate accelerations and decelerations of the sinus node in response to respiration. One also may observe tachyarrhythmias such as atrial tachycardia or AV reciprocating tachycardia rather than sinus rhythm.

Atrioventricular Conduction

One assesses conduction both by measurement of the PR interval and the relationship of P waves to QRS complexes. The PR interval is age, activity, and heart rate dependent. Impaired AV conduction is described as first-, second-, or third-degree AV block. Abbreviated conduction, manifested by a short PR interval, occurs in WPW syndrome, glycogen storage disease, and the presence of a low atrial pacemaker located closer to the AV node.

Atrial Enlargement and Hypertrophy

The right atrium is to the right, superior, and anterior to the left atrium. During normal sinus rhythm, the right atrium begins to depolarize before the left atrium, so that the first 0.04 to 0.06 seconds of the P wave are due mostly to right atrial activation. Thus, effects of atrial enlargement may be manifested early, to the left and inferior (right atrial) or late and posterior (left atrial) portion of the P wave. If sinus rhythm is not present, for example, with an ectopic atrial rhythm or an electronic atrial pacemaker, these criteria are not applicable. The ECG criterion for right atrial enlargement is the presence of a peaked, tall P wave in lead II (Fig. 15.3). The upper limit of normal for the P wave amplitude is 2.5 mm over the age of 6 months, and 3.0 mm from 0 to 6 months (Table 15.2). This can be accompanied by a biphasic or tall P wave in lead V1. The criteria for left atrial enlargement include a broad notched P wave in lead II (P-wave duration >0.10 to 0.12 seconds) and/or a deep, slurred biphasic P wave in V1, particularly when the terminal negative component is broad and deep. Biatrial enlargement is considered to be present when signs of both right and left atrial enlargement are present.

Ventricular Depolarization

Normally, ventricular depolarization occurs virtually simultaneously at many sites, resulting in a QRS of brief duration. QRS duration is age dependent (Table 15.2). It is <80 ms from infancy through age 8 years, and <90 ms throughout childhood and early adolescence. QRS duration is an objective measure that can be determined reliably using computerized ECG recording systems. QRS duration may be prolonged by right or left bundle branch block (LBBB), ventricular preexcitation, or a ventricular pacemaker. The term *intraventricular conduction delay* is reserved for those situations when QRS is prolonged but does not fit any of the above categories.

Axis Deviation

Axis is an ECG measurement derived from the equivalent dipole model. The electrical axis is the direction of the predominant vector of a wavefront in the frontal plane. It is a physiologic abstraction and an oversimplification because it does not take into account the time-dependent changes in vector forces that occur during atrial and ventricular depolarization. Still, it has been a popular ECG measure, and some prefer to call the axis the mean frontal plane vector. The simplest way to present the concept is to represent leads I and aVF on a Cartesian system (Fig. 15.4), designating lead I as 0 (left) to 180 degrees (right) and lead aVF as 90 (inferior) to 270 degrees (superior), with the other limb leads corresponding to other angles in the frontal plane. The axis can be calculated for all three waves of the ECG. For example, using the system shown in Figure 15.4, one first determines a quadrant by looking at leads I and aVF. Once the quadrant is established, the frontal lead, which is most isoelectric, is identified. The mean QRS axis is perpendicular to this lead.

QRS and P axes are measured reliably by automated ECG interpretation systems, and normal values have been tabulated (4,32,33). However, the same concepts can be applied to the ST segment, initial part of the QRS complex, and so on.

Frontal plane QRS axis deviation is age dependent. Right axis deviation is present when the QRS axis is more positive

Figure 15.3. A 6-month-old with tricuspid atresia and normally related great vessels. The ECG shows right atrial enlargement and left axis deviation.

Figure 15.4. Reference frame for the frontal plane according to Einthoven's equilateral triangle. The lines are drawn through the center to the negative terminus of each lead. Thus, the 360 degrees are divided into multiple 30-degree sections.

than normal, and left axis deviation is present when the QRS axis is less than normal. Right axis deviation is a criterion for right ventricular hypertrophy (RVH), albeit a very poor one. In pediatric patients, left axis deviation is not a criterion for left ventricular hypertrophy (LVH). The QRS axis is *superior* when it is between -60 and -100 degrees. The axis is *indeterminate* (neither left nor right or northwest) when it is between -100 degrees and $+210$ degrees.

The most important pattern in pediatric patients is the so-called abnormally superior vector or abnormally superior axis. This occurs in patients with AV septal (canal) defects. The main QRS axis is superior, but the initial forces are inferior,

so that leads II, III, and aVF inscribe a small r wave followed by a large S wave. This pattern of initial forces separates the abnormally superior vector from other causes of axis deviation (Fig. 15.5).

Bundle Branch Block

Bundle branch block exists when there is prolongation of the QRS. Because the distal conduction system is divided into left and right bundle branches, which depolarize the left and right ventricles respectively, block in one of the bundle branches will lead to delayed activation of the corresponding ventricle. Thus, the diagnosis is based on knowledge of anatomy and analysis of the terminal vector forces of the QRS complex. For example, because the right ventricle is to the right, anterior and superior in relation to the left ventricle, right bundle branch block (RBBB) will give rise to terminal forces that are rightward, anterior, and superior. Furthermore, the left bundle normally divides into two fan-like sheets of specialized conduction tissue: The anterior and posterior fascicles. Delay or block in either fascicle will result in a characteristic ECG pattern.

In practice, it is not always possible to differentiate bundle branch block from severe ventricular hypertrophy. This is because severe hypertrophy can result in a prolonged QRS that mimics bundle branch block. In the hypertrophied heart, endocardial activation is presumed to be on time, but epicardial activation is delayed owing to prolonged conduction time through the hypertrophied ventricular wall.

Right Bundle Branch Block

In RBBB, the QRS complex is wide and has a characteristic morphology of a rapid initial deflection followed by a slurred slower portion of the QRS. This reflects the rapid depolarization of the left ventricle followed by the slower depolarization of the right ventricle through ventricular muscle. The criteria for complete right bundle branch block includes a QRS above the upper limit for age in combination with normal initial forces and terminal conduction delay that is directed anteriorly, to the right and superior (wide and slurred S in leads I, V5, and V6; slurred R waves in leads aVR, V1, and V2; and wide and slurred S in leads II, III, and aVF) (Fig. 15.6).

The most common cause of RBBB is surgical closure of ventricular septal defects, especially in tetralogy of Fallot. When

Figure 15.5. Newborn with a complete AV septal (canal) defect. Note typical abnormally superior axis (northwest axis) along with right atrial enlargement.

Figure 15.6. A 3-year-old following repair of tetralogy of Fallot. Note Q waves in inferior leads, documenting normal left anterior fascicular conduction.

the ECG demonstrates RBBB, it is not possible to diagnose RVH. The usual markers of ischemia also are lost because of associated ST- and T-wave abnormalities.

"Incomplete" Right Bundle Branch Block

An RSR prime pattern in lead V1 with a normal or slightly prolonged QRS duration has been termed incomplete RBBB. However, this pattern of ventricular conduction occurs in normal children. Further complicating matters, this pattern commonly occurs with right ventricular overload and frequently is present in patients with secundum atrial septal defects. Because of the prevalence of this pattern in normal children, it is perhaps better to refer to this as minor right ventricular conduction delay and not necessarily abnormal.

Left Bundle Branch Block

Just as delay or block in the right bundle branch results in RBBB, delay or block in the main left bundle branch results in late activation of the left bundle and LBBB. The QRS is prolonged, slurred, and directed leftward, posteriorly, and

inferiorly. The criteria for LBBB include an abnormally prolonged QRS duration, absent normal initial forces (no Q waves in leads aVL and V6), and notched slurred QRS complexes that are directed leftward and posteriorly (QS or rS in lead V1 and a tall notched R wave in lead V6).

LBBB is uncommon in children. It is usually the result of surgery on the left ventricular outflow tract. It also occurs with hypertrophic cardiomyopathy, myocarditis, or dilated cardiomyopathy (Fig. 15.7). As with RBBB, it is difficult, if not impossible, to assess hypertrophy and ischemic changes when LBBB is present.

Left Anterior Hemiblock

Normally, the left anterior fascicle is responsible for activation of the anterior and superior portion of the left ventricle, which occurs just ahead of activation of the posterior-inferior region by way of the left posterior fascicle. Block in the left anterior fascicle results in sequential activation of the left ventricle. The posterior-inferior region of the left ventricle is activated prior to the anterior-superior region. This results in abnormal QRS

Figure 15.7. Left bundle branch block in a 15-year-old patient following resection of a subaortic membrane.

activation, with two sequential vectors: The initial forces are directed inferiorly and then spread in an anterior and superior fashion. This produces marked left axis deviation (<-30 degrees) with an rS in the inferior limb leads (II, III, and aVF). The QRS is normal or only minimally prolonged.

This conduction abnormality is relatively rare in children without congenital heart disease. It can occur with myocarditis, ischemia, or after cardiac surgery on the left ventricular outflow tract or ventricular septal defect closure. Tricuspid atresia and AV septal defects have ECG findings consistent with left anterior hemiblock (abnormally superior vector or axis) (34,35). However, these conditions do not have a true conduction defect, but rather, are related to the abnormal development of the conduction system.

Left Posterior Hemiblock

The activation sequence in left posterior hemiblock is the opposite of that seen with anterior hemiblock. The left ventricle depolarizes first in the anterior and superior region and then in the posterior and inferior portion. This produces an axis that is oriented rightward and inferiorly (120 degrees) with a normal QRS duration. Initial forces are directed superiorly (Q waves in leads II, III, and aVF). Left posterior hemiblock can be difficult to diagnose because most infants will have a rightward axis; this diagnosis should be reserved for a sudden change in axis between serial ECGs. It can result from surgical trauma and myocarditis.

Bifascicular Block

RBBB in combination with left anterior hemiblock occurs most commonly following repair of tetralogy of Fallot (10% of such patients). The ECG reflects the combination of these two conduction abnormalities. The initial forces, which in RBBB reflect only the left ventricle, initially are directed inferiorly and subsequently superiorly owing to left anterior hemiblock. The rest of the QRS complex reflects the characteristic terminal rightward and superior slurring of RBBB (Fig. 15.8).

RBBB and left posterior hemiblock is rare and difficult to diagnose by ECG. It is characterized by RBBB with initial rightward forces. Because most children who develop RBBB following surgery have preexisting RVH, it is difficult to distinguish RBBB with left posterior hemiblock from preexisting RVH.

Preexcitation

Preexcitation describes an abnormal depolarization of the ventricle prior to normal conduction through the His-Purkinje system. This takes place because of activation via an accessory connection between the two chambers.

Wolff-Parkinson-White Pattern

Wolff-Parkinson-White syndrome results from the presence of an accessory pathway that connects the atria directly to ventricular muscle. Conduction occurs both across the normal conduction system (AV node and His-Purkinje system) and across the accessory pathway. The ECG has a characteristic appearance of a short PR interval and a wide QRS complex (see Chapters 17 and 18). A delta wave or slurred upstroke of the QRS, indicating conduction from atrial to ventricular muscle, is characteristic of the syndrome. The terminal part of the complex may be wide or narrow, depending on the degree of conduction via the AV node. Children who have this finding are subject to episodes of reciprocating AV tachycardia. To diagnose WPW syndrome, a patient must have both the characteristic pattern of preexcitation as well as episodes of supraventricular tachycardia or atrial fibrillation. Therefore, the electrocardiographer should read the ECG as showing a "WPW pattern" or "ventricular pre-excitation."

Mahaim Pathway

The Mahaim pathway is a particular type of accessory pathway that inserts into the right bundle branch or right ventricle and incorporates AV node-like tissue. There are several types. The most common is the atriofascicular pathway, with nodofascicular and fasciculoventricular pathways being less common (36). A Mahaim pattern of pre-excitation is one in which there is a widened QRS with an appearance similar to that in WPW, but in which there is a normal PR interval.

Lown-Ganong-Levine Syndrome

This entity exists when there is a short PR interval without a QRS abnormality in association with episodes of abnormal tachycardia. With the advent of invasive electrophysiologic testing, this entity has essentially disappeared from the literature, most likely owing to the fact that there does not seem to be a clear electrophysiologic correlate to the

Figure 15.8. Right bundle branch block with left anterior hemiblock following complete repair in an 11-month-old with tetralogy of Fallot and AV septal (canal) defect. Note lack of initial Q waves in leads II, III, and aVF.

so-called Lown-Ganong-Levine (LGL) syndrome. Most of these patients, in fact, were adults who had atrial fibrillation with fast AV node conduction. When there is a short PR interval with a normal QRS morphology and duration, one should simply read the ECG as showing a short PR interval rather than the LGL pattern.

Hypertrophy

Criteria for ECG determination of ventricular hypertrophy rely largely on whether QRS voltages in specific leads exceed normal values. The criteria were derived empirically, based on studies of normal infants or on comparison of ECG measurements with findings at cardiac catheterization, surgery, or autopsy. Interpretation of criteria for hypertrophy depends on the assumption that cardiac-torso geometry is normal or near normal and the ventricular depolarization sequence is normal (i.e., no bundle branch block). Because of the proximity effect, the closer the heart is to a particular precordial lead, the greater the observed voltage, regardless of the underlying cardiac pathology. Limb leads give rise to little or no proximity effect (6). This effect is particularly important in infants who have relatively thin chests. Consequently, some leads are better for determining certain types of hypertrophy. Still, if one approaches the problem of ventricular hypertrophy by thinking in terms of the vector forces involved, combined with the knowledge of cardiac anatomy and the relative positions of the right and left ventricle in the chest, the criteria for RVH and LVH will not seem entirely arbitrary. That is, the right ventricle is to the right, anterior, and superior, so that increased forces to the right, anterior, and superior suggest RVH. Likewise, the left ventricle is to the left, inferior, and posterior, and increased forces directed to the left, inferior, and posterior suggest LVH. Leads V5 and V6 may be used to judge left-right forces, leads V1 and V2 can be used for judging anterior-posterior forces, and aVF is the best lead for judging inferior-superior forces.

Left Ventricular Hypertrophy

In general, criteria for LVH are based on QRS voltage criteria and repolarization criteria. The voltage criteria involve voltage increase, and the repolarization criteria refer to the shift of the T-wave axis in the direction opposite to the QRS. Voltage criteria involve R and S waves in leads V1, V6, and aVF

and Q wave amplitude in lead V6. These measurements are compared with known normal standards that vary with age. The repolarization criteria refer to T-wave negativity in the lateral precordial leads and the angle (>100 degrees) between the frontal plane QRS and T axis.

R-wave amplitude greater than the 98th percentile for age in lead V6 and S-wave amplitude greater than the 98th percentile in lead V1 have been used to predict LVH. Unfortunately, hypertrophy may be present with normal left-sided forces, and normal children can have R waves in lead V6 that are above the 98th percentile. The large S wave in lead V1 owing to increased posterior forces is a much better criterion for LVH (Fig 15.9).

Patients with LVH usually have increased inferior forces manifesting a tall R wave in aVF, but this also may occur in RVH. In the absence of RVH, this criterion is helpful in supporting a diagnosis of LVH, particularly in a patient with prominent mid-precordial voltages because the limb leads are not prone to proximity effect.

In newborns, if an adult pattern of R-wave progression is evident, rather than the neonatal pattern, LVH is likely. That is, when a newborn manifests small R waves and deep S waves over the right precordium progressing to tall R waves and small S waves in the left lateral precordium, it suggests that there is left ventricular dominance. This corresponds to the vectorcardiographic finding of a wide-open counterclockwise loop in the horizontal plane.

T-wave abnormalities are the most reliable indication of LVH. A so-called strain pattern consists of inverted T waves in the inferior leads (II, III, and aVF) and left precordial leads (V5 and V6). One can compare the frontal plane T-wave axis with the QRS axis, and the difference between these is the QRS-T angle. Normally it is very small, and a wide QRS-T angle of >100 degrees is supportive of the diagnosis of LVH but is not specific (Fig. 15.9). T-wave abnormalities in LVH sometimes can be associated with depression of the ST segment. T-wave inversion also may be a sign of ischemia or myocardial inflammation; thus, these causes must be excluded prior to the diagnosis of LVH being made.

Left axis deviation is supportive of the diagnosis of LVH, especially in infancy. Left anterior hemiblock also may cause left axis deviation.

Abnormally prominent Q waves in the left lateral precordium (leads V5 and V6) may result from hypertrophy of the

Figure 15.9. An 8-month-old male with left ventricular hypertrophy. Note that the ECG is half-standard, and there is a T wave abnormality.

left ventricular portion of the interventricular septum, or perhaps from abnormal position of the left relative to the right ventricle owing to hypertrophy. A dilated volume-loaded left ventricle, which occurs with aortic valve insufficiency or patent ductus arteriosus, tends to produce deep Q wave in the lateral leads. On the other hand, with severe LVH, as might be seen with severe pressure loading, small or absent Q waves occur.

Right Ventricular Hypertrophy

Criteria for RVH are more specific than for LVH and include voltage and repolarization criteria. Because of normal right ventricular predominance in the neonate and the rapid changes in T-wave vectors in the first 2 weeks of life, the ECG interpretation of RVH in infants may be difficult.

R-wave amplitude in lead V1 that is greater than the 98th percentile for age is a very specific finding for RVH beyond the neonatal period. It has been used to estimate right ventricular pressure in isolated pulmonary stenosis using the following formula: Peak systolic right ventricular pressure = R-wave height, in mm \times 5 (34). An R wave in V1 that is >20 mm correlates with a right ventricular pressure that is at least systemic (37).

An abnormally deep S wave in V6 (>98 th percentile) is a very sensitive indicator of RVH. It often occurs in patients with increased right ventricular pressure secondary to chronic lung disease. When this pattern occurs with right atrial enlargement, it is characteristic of cor pulmonale. This criterion is less specific than the R wave in lead V1 because of the possibility of posterobasal LVH, in which large terminal superior and rightward forces result from hypertrophy of this late-activating portion of the left ventricle.

The R/S ratio is well established for various ages. If it is abnormally increased in lead V1, or abnormally decreased in lead V6, RVH is likely. However, it is rare for an abnormal R/S ratio to occur as an isolated finding, and this criterion should, therefore, be applied in conjunction with other findings of RVH.

T-wave orientation changes with age. Normally, it is upright until 4 to 7 days of age. Between 1 week of age and adolescence it is negative, and reverts to upright again in many individuals in adolescence and adulthood. An upright T wave after 7 days of age but before adolescence is a sensitive indicator of increased right ventricular pressure. The sensitivity

of this measure increases when R-wave amplitude also is considered. Mild RVH is manifested by normal R-wave amplitude but an upright T wave. Moderate RVH is manifested by increased R-wave amplitude and an upright T wave, whereas severe RVH is manifested by an increased R-wave amplitude and inversion of the T wave (Fig. 15.10).

A qR pattern also can be indicative of RVH, especially in conjunction with a tall R wave [typically >10 mm (Fig. 15.11)]. It also occurs with l-looping of the ventricles (abnormal septal depolarization), anterior myocardial infarction, and WPW syndrome.

An RSR prime pattern can be associated with right ventricular volume overload, as seen with atrial septal defects, but also may be a normal finding. It should be used to diagnose RVH only when the R prime amplitude is large.

Right axis deviation alone is not a criterion for RVH, but can be used to support other findings suggestive of RVH. Another cause of right axis deviation is left posterior hemiblock.

As in LVH, the R-wave progression across the precordial leads may be helpful. The neonatal pattern, consisting of tall R waves and small S waves in the right precordium, progressing to small R waves and deep S waves in the left lateral precordium, suggests right ventricular dominance (Fig. 15.12). When this pattern occurs in older children, rather than the normal adult-type R-wave progression, it suggests severe RVH. This corresponds to a completely clockwise loop in the horizontal plane.

Biventricular Hypertrophy

The diagnosis of biventricular hypertrophy (BVH) is made most easily when there are clear criteria present for both RVH and LVH. This often is manifest by normal R-wave progression across the precordium, but with increased voltages, so that there are both large R and S waves in leads V1 and V6. Proximity effect may produce prominent voltages in normal children in the mid-precordial leads (V3 to V5) without increases in leads V1 or V6 or any of the limb leads. In this situation, one should not diagnose hypertrophy, but should instead note the presence of prominent mid-precordial voltage. However, if the total voltage (R plus S) in lead V4 is >60 mm, BVH is likely (the Katz-Wachtel criterion).

Some electrocardiographers diagnose BVH when there are clear criteria for hypertrophy of one chamber and normal

Figure 15.10. A 4-month-old with hypoplastic left heart syndrome. Note that the tracing is recorded at half-standard.

Figure 15.11 A 3-year-old following repair of truncus arteriosus with significant conduit obstruction. Note the qR in the right precordial leads, as well as the terminal rightward conduction delay, in this case due to hypertrophy.

voltages arising from the other chamber (e.g., >98th percentile R in V6 with greater than mean S in V6). They reason that the predominance of one chamber cancels or masks voltage from the other chamber, and therefore normal voltages could reflect hypertrophy. Although this approach makes some sense, in practice it seems to be dependent on the magnitude of the hypertrophy involved (i.e., it is more likely to be true if one chamber is severely hypertrophied). This criterion also suffers from the oversimplified viewpoint that R and S waves arise from one chamber only. For example, it would be incorrect to believe that for patients with LVH, the S wave in V6 and the S wave in lead aVF reflect only right ventricular forces, because the posterobasal portion of the left ventricle depolarizes later than the rest of the left ventricle. LVH also may include the posterobasal portion of the left ventricle, with normal to increased S waves in leads V6 or aVF without BVH.

Low QRS Voltage

Reduced QRS voltage is a nonspecific finding that may occur with various conditions, including myocarditis, pericardial

effusion, and generalized edema. Low voltage is present when the QRS amplitude is <5 mm in all limb leads and <10 mm in all precordial leads. While not always present, when associated with ST-segment change, it is characteristic of myocarditis.

Initial Forces

The Q wave occurs at the beginning of the QRS complex. One normally finds a small (<4 mm) Q wave in leads V5 and V6, and aVF. This is because normal initial depolarization, made up of several different areas of endocardial activation including the septum, is rightward, superior, and anterior. There are only a few specific situations when the presence or absence of certain types of Q waves may be of clinical significance. If the QRS duration is prolonged, no specific significance can be attached to Q waves. For the diagnosis of myocardial infarction, Q-wave duration should be ≥ 40 ms (38). Q-wave amplitude is lead dependent but in all cases should exceed 4 mm. A qR pattern in lead V1 signifies RVH, and deep Q waves in leads II, III, aVF, V5, and V6 are indicative of left septal hypertrophy, usually as part of LVH. Finally, in patients with

Figure 15.12 A 3-day-old male infant with critical coarctation. The ECG shows RVH. Note that all leads are half-standard.

congenitally corrected transposition of the great arteries and ventricular inversion, initial forces are posterior and to the left, producing a small Q wave in V1 or a qS complex, with absence of the normal Q wave in leads V5 and V6.

Ventricular Repolarization

Considered from the standpoint of a single cardiac cell action potential, repolarization is simply defined and begins immediately following depolarization. However, viewed from the perspective of the whole heart, repolarization is more difficult to characterize (39). In the normal heart, the subendocardium depolarizes before the subepicardium, but the subepicardium repolarizes before the subendocardium. This figures prominently in ECG features during the ST segment and T wave. There is an age-dependent overlap between the end of depolarization and the onset of repolarization. In childhood, repolarization potentials appear on an average of 10 ms before the end of ventricular depolarization (J point) (40).

QT Interval

There has been considerable debate regarding the best way to measure the rest and exercise QT interval. In supine patients at rest, the technical difficulty is determination of the end of the T wave, which may be fused with the U wave as it gradually blends with the baseline (40,41). Furthermore, Davignon et al. (32) demonstrated that the QT interval is both age and heart rate dependent. Attempts to correct for heart rate usually involve Bazett's formula ($QT_c = QT \text{ interval divided by the square root of the preceding R-R interval}$, where QT_c is the corrected QT interval). However, this may be inaccurate at low heart rates, often seen in adolescents. A number of alternative proposals have been made for correcting the QT (42). Technical problems are compounded during exercise because of the difficulty in identifying the ECG baseline. They also are complicated by variations in the RR interval that occur in children due to sinus arrhythmia. The choice of RR interval to be measured is critical in calculating the corrected QT interval. Garson (43) has suggested measuring the shortest RR interval. Calculating the QT_c from that interval, he found that a cutoff of 460 ms for QT_c identifies 98.4% of known long QT syndrome patients but only 3.8% of normal control subjects. In patients with QRS abnormality, and especially QRS prolongation due to bundle branch block, measurement of the QT_c is less useful, as it tends to be quite long in otherwise normal patients. The corrected JT interval has been proposed as a potential solution to this conundrum, and although normal standards for this measurement exists, it is not yet clear that this method reliably separates patients with prolonged QT syndrome and RBBB from other patients with RBBB (44).

The QT interval may be prolonged on a congenital basis (45,46) or as the result of antiarrhythmic drugs or electrolyte imbalance (47). The significance of a prolonged QT interval in an asymptomatic child is hard to determine. There seems to be little disagreement that a QT of 400 ms is normal and a QT of 480 ms is abnormal. However, there is disagreement as to the significance of intermediate values, especially in asymptomatic patients. Family history is, of course, important. Even in patients with pathologic prolongation of the QT interval, no ECG feature has been identified (not even the QT interval) that predicts which patients will develop symptoms or torsades de pointes (48).

ST Segment, T Waves, and U Waves

ST Segment

Identifying the true baseline is extremely important when analyzing the ST segment. This is an important practical problem

when the heart rate is increased as during exercise or with fever. ST segments >1 mm are said to be elevated and ST segments <-0.5 mm are considered depressed. However, in an analysis of average (0 to 50 ms) ST-segment potentials, the maximum and minimum potentials were age dependent. Maximum potentials (1.1 to 3.7 mm) occurred during adolescence. Minimum ST-segment potentials (0.4 to 1.2 mm) occurred during childhood (40,41). Interpretation of apparent ST-segment abnormalities requires careful attention to the clinical situation and important age-dependent and technical limitations.

T Waves

The sequence of ventricular depolarization, as characterized by the time difference between the earliest and latest area to depolarize, is an important determinant of the T wave (i.e., asynchronous depolarization influences the ECG patterns). Abnormalities of depolarization have a direct effect on repolarization. Therefore, T-wave abnormalities may be entirely owing to QRS abnormalities. Such abnormalities are termed secondary T-wave abnormalities as opposed to primary T-wave abnormalities, which reflect actual abnormalities of repolarization not simply caused by changes in the QRS (49).

U Waves

Little is known about the source or significance of U waves. They are quite common in young people, but Spach et al. (40,41) did not find them in children <8 years of age. U waves usually are apparent in the mid-precordial leads (V2 to V5), and they often overlap the T wave, resulting in TU fusion. The latter feature may complicate measurement of the QT interval. The amplitude of U waves is about 10% that of T waves (range 4% to 28%). The U-wave amplitude is heart rate sensitive. When U waves are large and difficult to separate from the T wave, they may indicate prolonged QT syndrome. On the other hand, long QT syndrome often is misdiagnosed in the presence of prominent mid-precordial U waves (50).

Specific Abnormalities Affecting the ST Segment, T Wave, and U Wave

Early Repolarization
